CHAPTER 132

ACQUIRED DISORDERS OF PLATELET FUNCTION

Reyhan Diz-Küçükkaya and José A. López

Acquired disorders of platelet function are among the most common hematologic abnormalities, a reflection of the sensitivities of platelets to external and internal perturbations. The clinical challenge in evaluating acquired disorders of platelet function is to determine whether observed derangements in platelet function pose a threat to the patient. Although platelet function can be altered to predispose to either hemostatic or thrombotic disorders, this chapter deals primarily, but not exclusively, with platelet disorders that may compromise hemostasis. We attempt also to guide clinicians in trying to determine the clinical importance of these disorders, but the marked variations in bleeding risks associated with any particular disorder of platelet function make this a difficult task. Bleeding in patients with acquired platelet dysfunction is likely to occur less frequently and predictably than in those affected by severe inherited platelet disorders such as Bernard-Soulier syndrome or Glanzmann thrombasthenia and may manifest only in the setting of trauma or surgery or in the presence of additional hemostatic defects.

The laboratory evaluation of these patients may illuminate these disorders (see Chapter 131) but may offer little concrete guidance in management. Acquired platelet defects (Table 132-1) often exhibit abnormal laboratory test results, such as a prolonged closure time on a platelet function analyzer or abnormal aggregation in response to added agonists. Historically, the bleeding time was used to evaluate bleeding risk in patients with jaundice or uremia; but it measures hemostasis only in one vascular bed (the skin) and bears inherent interoperator variability. These platelet assays are useful as research tools; however, defects as quantified by laboratory tests, including the bleeding time, do not correlate precisely with the risk of bleeding and thus are not predictive of bleeding in these patients. Additionally, some acquired platelet disorders increase the risk of thrombosis rather than bleeding, a risk for which there is currently no effective screening test. Last, tests that depend on assessing the functions of platelets ex vivo do not assess the contributions of labile substances from the endothelium (see Chapter 125) and occasionally (as in platelet aggregometry) lack the component of flow, a key component of in vivo platelet function.

DRUGS, FOODS, AND ADDITIVES THAT AFFECT PLATELET FUNCTION

The most common causes of acquired platelet dysfunction are drugs. In a large prospective study, 5649 unselected adult patients were screened preoperatively for hemostatic defects with activated partial thromboplastin time (aPTT), prothrombin time (PT), platelet counts, platelet function analyzer (PFA-100) testing, and a questionnaire regarding bleeding history.[1] Bleeding history was positive in 628 patients (11.1%), and impaired hemostasis was verified in 256 (40.8%) of these patients. Of these 256 patients, 162 (63.28%) were found to have acquired platelet dysfunction. Antiplatelet drugs or nonsteroidal antiinflammatory drugs (NSAIDs) were responsible for the acquired platelet dysfunction in 147 patients and antibiotics in 10 patients.

Numerous drugs affect platelet function (Table 132-2). For several, inhibition of platelet function is their intended effect (Fig. 132-1); for most, platelet dysfunction is an unintended and undesired side effect. Drug-induced platelet function abnormalities do not usually cause a clinically significant problem in healthy individuals. However, these drugs may increase the bleeding risk with interventions (e.g., surgery, biopsy), trauma, or in the presence of other hemostatic defects, such as those associated with cirrhosis or uremia. Antiplatelet agents are discussed more fully in Chapter 151. For all of these drugs, their effects on platelet function are defined by an abnormality of platelet aggregation, but their contribution to a risk of excessive bleeding is definitively established only for aspirin, clopidogrel, ticlopidine, and inhibitors of $\alpha_{IIb}\beta_3$ function.

ANTIPLATELET DRUGS

Aspirin

Aspirin has been in routine use worldwide for more than 100 years and is still by far the most common agent associated with platelet dysfunction.[2] The antipyretic and analgesic effect of willow bark was first recorded by Galen. In 1826 and 1828, Leroux and Buchner isolated a compound from willow bark that they called *salicin* (which means *willow* in Latin).[3] In 1897, a German chemist, Felix Hoffman from the Bayer Company, inspired by his father's severe arthritis and the untoward side effects of salicylic acid, discovered a method to convert salicylic acid, the active compound in willow bark, to a compound with less gastrointestinal (GI) toxicity, acetyl salicylic acid (aspirin).[4] However, with Hoffmann's subsequent synthesis of heroin from morphine, commercial development of aspirin was relegated to the back burner for a number of decades.[5] Aspirin was widely used for rheumatic fever in the 1940s. In the 1950s, case reports and uncontrolled studies were published suggesting that aspirin could prevent myocardial infarction and stroke.[5,6] The clinical importance of the antithrombotic effect of aspirin was clearly demonstrated in a study of 22,071 physicians who received either 325 mg of aspirin or placebo every other day over the course of 5 years.[7] Those receiving aspirin had a 44% decreased incidence of myocardial infarction. In a large meta-analysis, it was shown that aspirin reduced death from vascular events by 15% and nonfatal vascular events by 30%.[7] The primary mechanism by which aspirin impairs hemostasis is through irreversible acetylation of the enzyme cyclooxygenase-1 (COX-1), an early enzyme in the synthetic pathway that produces the potent platelet agonist, thromboxane A_2 (TXA_2). Because platelets have no nuclei and therefore retain only a limited capacity to synthesize new proteins, a single low dose of aspirin (40-100 mg) or as little as 10 mg taken daily for 1 week can completely inhibit TXA_2 production and therefore impair the function of a cohort of platelets for their circulating life span. Aspirin also acetylates the isoform of COX present in endothelial cells, COX-2; COX-2 acetylation blocks synthesis of prostacyclin, a strong inhibitor of platelet function.[8] However, COX-2 is markedly less sensitive than COX-1 to inhibition by aspirin,[2] and endothelial cells, unlike platelets, are able to synthesize new enzymes quite rapidly.[9]

Platelets exposed to aspirin either in vivo or in vitro predictably demonstrate impaired aggregation in response to epinephrine, adenosine diphosphate (ADP), arachidonic acid, and low concentrations of collagen and thrombin,[10] a result of defective TXA_2 production.

Table 132-1 Acquired Disorders of Platelet Function

Drugs, Foods, and Additives
Drugs: see Table 132-2
Food and additives: omega-3 fatty acids, ethanol, ginger, onion, garlic, black tree fungus, *Gingko biloba*, cumin, turmeric, tonic water, caffeine, others
Clonal Disorders
Clonal hematologic diseases
Myeloproliferative neoplasms
Paroxysmal nocturnal hemoglobinuria
Paraproteinemias
Leukemias and myelodysplastic syndromes
Solid tumors
Systemic Metabolic Disorders
End-stage renal disease
Liver diseases
Diabetes and hyperlipidemias
Platelet Dysfunction Related With Extracorporeal Circuits Miscellaneous
Hypothermia
Disseminated intravascular coagulation

Table 132-2 Drug-Induced Platelet Dysfunction

Anti-Platelet Drugs
COX inhibitor: aspirin
ADP receptor antagonists
Thienopyridines: clopidogrel, ticlopidine, prasugrel
Nonthienopyridines: ticagrelor, cangrelor
$\alpha_{IIb}\beta_3$ inhibitors: abciximab, eptifibatide, tirofiban
PDE inhibitors
Nonselective PDE inhibitors: pentoxifylline, caffeine, theophylline
PDE3 inhibitors: cilostazol, milrinone, anagrelide
PDE5 inhibitors: dipyridamole, sildenafil
Adenyl cyclase stimulators: epoprostenol, iloprost, beraprost
Drugs that adversely affect platelet function
NSAIDs: ibuprofen, naproxen, indomethacin
Cardiovascular agents
Calcium channel blockers: nifedipine, diltiazem, verapamil
β-Blocker: propranolol
Vasodilators: nitrates, nitroprusside
Diuretic: furosemide
Angiotensin II receptor antagonist: losartan
Antibiotics: β-lactams, amphotericin, hydroxychloroquine, nitrofurantoin
Psychiatric drugs: TCAs, fluoxetine, chlorpromazine, promethazine, trifluoperazine
Oncologic drugs: mithramycin, daunorubicin, BCNU, asparaginase, vincristine
Anesthetics: dibucaine, procaine, halothane
Plasma expanders: dextran, hydroxyl ethyl starch
Heparins and thrombolytic agents
Miscellaneous: clofibrate, statins, cocaine, ketanserin, radiographic contrast agents, antihistamines, immunosuppressive drugs

ADP, Adenosine diphosphate; *BCNU,* carmustine; *COX,* cyclooxygenase; *NSAID,* nonsteroidal antiinflammatory drug; *PDE,* phosphodiesterase; *TCA,* tricyclic antidepressant.

These agonists have therefore been defined as *weak* agonists, requiring that TXA_2 diffuse out of the platelet, bind to its receptor on the platelet membrane, and reinforce aggregation by promoting secretion from α and dense granules. Aspirin-treated platelets stimulated with these agonists demonstrate only a primary, reversible wave of aggregation without granule secretion. Stronger agonists (high concentrations of thrombin and collagen) do not require TXA_2 synthesis to cause platelet secretion and irreversible aggregation, which probably accounts for the observation that hemostasis in healthy aspirin-treated subjects is usually normal. Aspirin is a very effective antiplatelet agent when it is used long term even in small doses. In randomized controlled studies, aspirin has been shown to be effective in reducing the risk of ischemic stroke or transient ischemic attack at a dose of 50 mg/day and of unstable angina and severe carotid artery stenosis at 75 mg/day.[11-13] Higher doses of aspirin do not further reduce risk.

Aspirin may also have COX-independent actions that may affect coagulation. At the site of microvascular injury, platelets bind to exposed collagen, and coagulation is initiated by tissue factor concurrently. It was reported that low-dose aspirin (30 mg/day for 7 days) decreased thrombin formation in healthy volunteers.[14] Undas et al[11] used the same microvascular injury model and showed that aspirin at 75 mg/day for 7 days decreased the velocity of prothrombin consumption by 29%, thrombin generation by 29% and delayed both activation and maximum cleavage of factor XIII by thrombin. Interestingly, it was demonstrated that high cholesterol levels (>240 mg/dL) impair the antithrombotic effect of low-dose aspirin in a microvascular injury model.[5]

In contrast to the antiplatelet effect of aspirin, which appears unrelated to the dose above small threshold doses, GI mucosal toxicity is dose related.[15] The mechanism of mucosal injury appears to be distinct from the effect on hemostasis, involving ionic trapping of aspirin within gut mucosal cells[16] and diminished synthesis of protective gut prostaglandins.[17,18] The inhibitory effect of even a single dose of aspirin on gastric prostaglandin synthesis is prolonged, with one study showing that gastric COX activity was still 57% suppressed 72 hours after a single 325-mg dose of aspirin.[19] Bleeding may originate from discrete ulcers or diffuse mucosal damage and is more common to arise from the upper GI tract. The risk of bleeding is increased even with doses of aspirin as low as 10 to 30 mg/day[20]; the protective effect of resistant coatings is unproved.[21] Recently, a nitric oxide–donating form of aspirin (NCX-4016) has been shown to enhance the cardioprotective effect of aspirin while sparing the GI tract.[22] The GI risk of aspirin is increased in elderly adults (older than 65 years of age) and in those with concomitant medical conditions, such as cardiovascular disease, as well as in those taking certain other medications, such as other NSAIDs.[21] Aspirin appears to delay the healing of gastric ulcers, possibly because it interferes with the release of growth factors from platelets, such as endostatin and vascular endothelial growth factor.[23]

Aspirin treatment was also associated with a small but significant increase in mucocutaneous bleeding as evidenced by easy bruising, hematemesis, melena, epistaxis, and an increased frequency of blood transfusion. Because low doses have been shown to be effective in preventing thrombosis, it is likely that the risk of bleeding can be reduced while maintaining an antiplatelet effect.

The response to aspirin therapy varies among individuals. Every day, the human body can produce approximately 10×10^{11} platelets, and this production can increase 10-fold if needed. The life span of platelets is 8 to 10 days, and every day nearly 10% to 12% of the platelets are replaced by new platelets. The capacity of the bone marrow to produce new platelets, the aspirin dosage, the aspirin exposure time (spot doses or regular use), and individual parameters may be different among individuals. The antiplatelet effect of aspirin can be screened by light-transmission aggregometry, flow cytometry, PFA-100, or other automated platelet aggregometers such as VerifyNow.

Assays of Aspirin Effect on Platelets

Light transmission aggregometry (LTA) measures platelet aggregation in response to various agonists. Although LTA is the gold standard for evaluating platelet functions, clinical use of LTA in screening of antiplatelet therapy is limited because of cost, complex assay procedures, and the need for expert interpretation. Flow cytometry assays

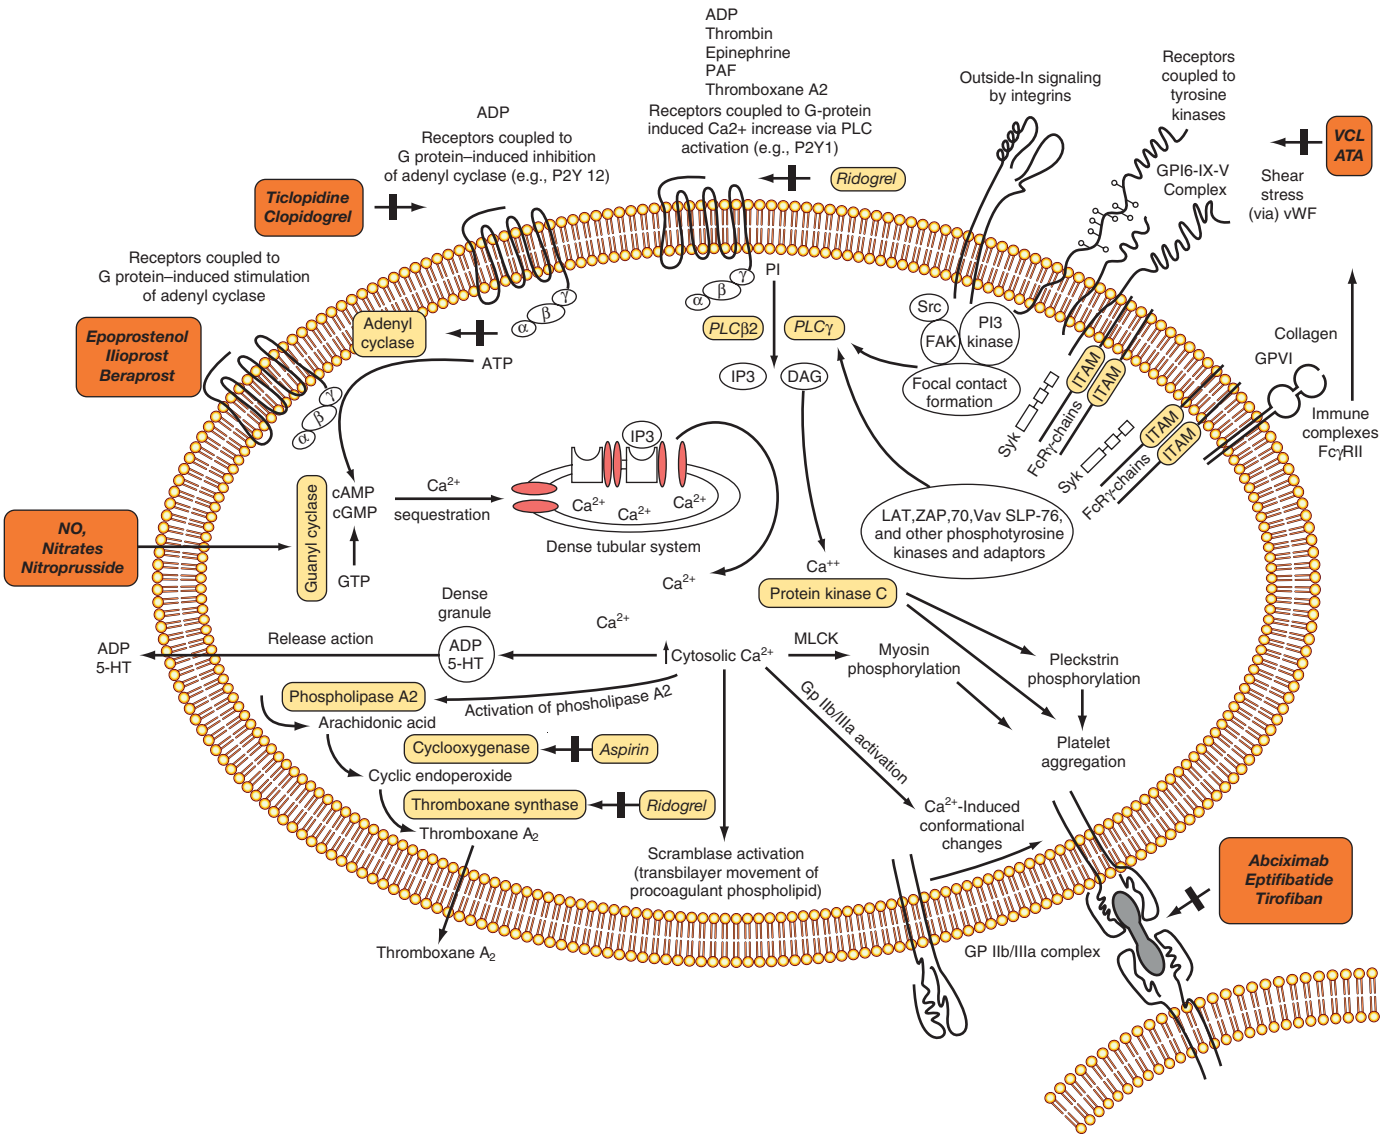

Figure 132-1 MECHANISM OF INHIBITION OF PLATELET FUNCTION BY VARIOUS DRUGS. Some of the drugs shown, such as Ridogrel, VCL (rA1 domain of von Willebrand factor), and ATA (aurin tricarboxylic acid), are not now used clinically. *ADP,* Adenosine diphosphate; *ATP,* adenosine triphosphate; *cAMP,* cyclic adenosine monophosphate; *cGMP,* cyclic guanyl monophosphate; *DAG,* diacylglycerol; *GP,* glycoprotein; *GTP,* guanyl triphosphate; *5-HT,* serotonin (5-hydroxytryptamine); *IP3,* inositol triphosphate; *ITAM,* immunoreceptor tyrosine-based activation motif; *MLCK,* myosin light chain kinase; *NO,* nitric oxide; *PAF,* platelet activating factor; *PI,* phosphatidylinositol; *PLA2,* phospholipase A2; TXA_2, thromboxane A_2; *vWF,* von Willebrand factor.

measure platelet surface glycoproteins, platelet activation markers, and platelet–leukocyte interactions using whole blood or platelet suspensions. The major limitations of flow cytometry analysis are the cost and need for expert interpretation. PFA-100 is an alternative to the bleeding time. This test assays platelet function under flow using two disposable cartridges, one coated with collagen–ADP and one coated with collagen–epinephrine. Citrated blood passes through an aperture within a coated membrane at the end of the cartridge, and the time for occlusion of this aperture is measured. Prolongation of the closure time is indicative of a defect in either platelets or von Willebrand factor (vWF).

VerifyNow is another cartridge-based system designed to assay platelet aggregation in the presence of antiplatelet drugs; the aspirin response is assessed by aggregation in response to arachidonic acid. The percentage of affected platelets (designated as aspirin reaction units [ARU]) determines the sensitivity to aspirin.[24,25]

The issue of aspirin resistance is hotly debated, with reported incidence rates varying from 0% to 57%.[26,27] How aspirin resistance is defined (clinical or laboratory) is important for clinical management. Clinical resistance is a definition applied to patients who experienced a new thrombotic event while receiving regular and effective-dose aspirin therapy. Because arterial thrombosis is a multifactorial process, the inhibition of one pathway of platelet activation may be insufficient to prevent thrombosis. Therefore, clinical resistance is mostly regarded as "drug failure."

Laboratory aspirin resistance is more complicated. In some patients, aspirin may not produce the expected effects on one or more screening laboratory tests. COX-1 gene polymorphisms (A842G, C50T, nucleotide changes designated) or platelet integrin α2 or β3 polymorphisms have been investigated in these patients, with conflicting results.[27-30] More recently, Voora et al[30] screened 11 single nucleotide polymorphisms (SNPs) reported to be associated with aspirin resistance in 3449 patients with coronary disease. They reported that none of these SNPs were associated with clinical or laboratory aspirin resistance. They suggested that use of these SNPs for guiding more aggressive aspirin therapy was not justified.

The most important issue in determining whether laboratory aspirin resistance is real is compliance: Schwartz et al[31] evaluated 190

patients with a history of coronary disease and receiving aspirin therapy. They investigated these patients on regular aspirin therapy, after withdrawal of aspirin for 7 days, and after an observed ingestion of 325 mg of aspirin. They found that 17 patients (9%) receiving regular aspirin therapy had aspirin resistance as defined by defective inhibition of arachidonic acid–stimulated platelet aggregation. After being observed to take the 325 mg aspirin, however, all patients but one displayed inhibition of aggregation. Similar results were observed in other studies.[32] These investigators concluded that noncompliance was the predominant cause of aspirin resistance. Other causes of aspirin resistance may include increased platelet turnover and increased COX-1 expression in new platelets[33] and overexpression of COX-2 in macrophages and endothelial cells.[34] It has also been reported that concomitant use of some NSAIDs such as ibuprofen and naproxen may prevent COX-1 inactivation in patients receiving low-dose aspirin.[25,35] Laboratory aspirin resistance in these cases is usually dose-dependent, and it can be eliminated by increasing the aspirin dose.[36]

It is clear that regular usage of aspirin increases the risk of bleeding in patients undergoing surgery or experiencing trauma. The likelihood that aspirin will cause bleeding is increased in the presence of other hemostatic defects. The risk of bleeding is increased if aspirin is given simultaneously with warfarin in high-intensity anticoagulation regimens (international normalized ratio, 3.0-4.5), but the occurrence of major hemorrhage was only moderately increased.[37] In a study in which lower intensity anticoagulation was examined, the risk of hemorrhage was not increased with the addition of low-dose aspirin.[38]

Similarly, aspirin may unmask mild hereditary disorders of platelet function.[39] For example, patients with mild von Willebrand disease often have a normal bleeding time that becomes markedly increased with aspirin therapy.[39] Conversely, aspirin given during treatment of acute coronary syndromes in combination with fibrinolytic and other antithrombotic agents does not appear to increase the incidence of major bleeding episodes,[40,41] with the exception of its combination with clopidogrel, which is associated with a slight increase in bleeding complications over treatment with aspirin alone.[42]

Adenosine Diphosphate Receptor Antagonists

The thienopyridines ticlopidine, clopidogrel, and prasugrel selectively and irreversibly inhibit ADP-mediated platelet activation and aggregation.[43] The use of ticlopidine has been greatly curtailed because of serious side effects such as agranulocytosis, thrombocytopenia, and thrombotic thrombocytopenic purpura.[44] ADP activates platelets by raising the concentration of cytoplasmic Ca^{2+} through influx from the extracellular fluid and mobilization from internal stores and by decreasing the concentration of intracellular cyclic adenosine monophosphate (cAMP) coupled to inhibition of adenylyl cyclase. ADP receptors can be divided into two groups: the G protein–coupled receptors, termed *P2Y,* and the ionotropic receptors, *P2X.* Platelets contain two P2Y receptors, $P2Y_1$ and $P2Y_{12}$, complexed to the heterotrimeric G proteins G_q and G_{i2}, respectively. ADP binding to $P2Y_1$ is necessary for platelet aggregation but is not sufficient. Rather, $P2Y_1$ is responsible for ADP-induced platelet shape change, and its engagement by ADP triggers a transient aggregatory response. $P2Y_{12}$, coupled to inhibition of adenylyl cyclase, mediates the amplification of the aggregation response and increases thrombus stability.[45] The thienopyridine derivatives have no effects on arachidonic acid metabolism and hence act synergistically with aspirin to inhibit platelet function.

The thienopyridines are all prodrugs of similar structure that produce active metabolites that bind irreversibly to $P2Y_{12}$, inhibiting ADP-mediated aggregation for up to 10 days after withdrawal of the drug, paralleling the platelet life span.[46] Because most platelet agonists require ADP for their full activity, the thienopyridines inhibit platelet activation by all agonists except strong agonists at high concentrations.[47] They have a further hypothetical advantage over aspirin in that they inhibit shear-induced platelet aggregation.[48]

Clopidogrel

Clopidogrel is administered orally. Approximately 15% of the absorbed prodrug is converted to its active form in the liver by the cytochrome P450 system. At lower doses of clopidogrel, the full pharmacologic effect requires 4 to 7 days, often doubling the bleeding time. When a rapid therapeutic effect is desired, clopidogrel can be given with a loading dose of 300 to 600 mg. At these doses, clopidogrel significantly impairs platelet function within 90 minutes of administration.[44,49-51] Dual antiplatelet therapy with aspirin and clopidogrel is associated with significant reductions of ischemic events in patients at risk for arterial thrombosis. Variability in the response to clopidogrel is well documented. The causes of clopidogrel resistance are many and include noncompliance; drug interactions (proton pump inhibitors may affect clopidogrel metabolism); and various genetic polymorphisms that control clopidogrel absorption, metabolic activation, and biological activity. Several studies have shown that loss-of-function polymorphic forms of CYP2C19 produce less of the active clopidogrel metabolites in both healthy individuals and patients, thus decreasing the antiplatelet effect of the drug.[52,53] These polymorphisms were also found to be associated with an increased risk of myocardial infarction, stroke, or death in studies of large cohorts.[54,55] The CYP2C19 loss-of-function alleles are quite common throughout the world (frequencies being ≈30% in Europeans, 40% in Africans, and more than 50% in Asians).[56] Increasing the clopidogrel dose in patients with loss-of-function CYP2C19 alleles produces better antiplatelet responses.[57] Because of the high prevalence of these alleles, monitoring the antiplatelet action of clopidogrel may be useful by LTA or other tests such as VerifyNow.[24] In patients who do not achieve the desired antiplatelet response with clopidogrel, prasugrel or ticagrelor may be an alternative.

Prasugrel

Prasugrel is a third-generation oral thienopyridine that is converted to its active form in the liver much more efficiently than is clopidogrel.[58] Prasugrel inhibits platelets more consistently than does clopidogrel, regardless of the CYP2C19 allele status of the person being treated.[54] This advantage over clopidogrel comes with a cost because the risk of major bleeding is elevated in prasugrel-treated patients. Three groups of patients are at particularly high risk of bleeding: those older than 75 years of age, those weighing less than 60 kg, and patients with history of stroke or transient ischemic attack.[59]

Ticagrelor

The chemical structure of ticagrelor is distinct from those of the thienopyridines. Ticagrelor is a cyclopentyltriazolo-pyrimidine that inhibits the ADP receptor reversibly and noncompetitively. Ticagrelor is given orally and is metabolized by the liver cytochrome P450 system to the active metabolite, which has a half-life of approximately 12 hours. The recommended dose is 100 mg twice daily. Ticagrelor has some advantages over thienopyridines such as rapid action, reversible and consistent antiplatelet effect with only a small increase in the risk of bleeding, and efficacy in patients with genetic resistance to clopidogrel. The major adverse side effect is dyspnea, which is of unknown mechanism. The drug was recently approved in the United States for the treatment of acute coronary syndromes.[60,61]

Platelet αIIbβ3 (Glycoprotein IIb/IIIa) Inhibitors

A myriad of pathways lead to platelet aggregation, the final common step being activation of the major platelet integrin $\alpha_{IIb}\beta_3$ to a ligand-competent form, which can bind multivalent ligands such as fibrinogen or vWF to cross-link the platelets into an aggregate. Conventional antiplatelet agents such as aspirin and clopidogrel each inhibit only one pathway leading to platelet aggregation, aspirin preventing

thromboxane production and clopidogrel blocking ADP receptors. Dual therapy with aspirin and clopidogrel improves the clinical benefit of antiplatelet therapy, but aggregation is still able to proceed through the action of other agonists such as thrombin. Because $\alpha_{IIb}\beta_3$ engagement is required for aggregation through all pathways, blocking this receptor inhibits platelet aggregation more effectively.

Inhibitors of $\alpha_{IIb}\beta_3$ work selectively and competitively to inhibit platelet aggregation.[62] These agents are intended to produce a transient effect akin to the defect in Glanzmann thrombasthenia, but there are important differences between the drug effect and the disease.

$\alpha_{IIb}\beta_3$ inhibitors have been used in tens of thousands of patients with various forms of cardiovascular disease. Although these agents share many similarities in their pharmacodynamics and therapeutic effects, they also have a number of clinically important pharmacokinetic differences.

Abciximab

The first $\alpha_{IIb}\beta_3$ inhibitor approved for clinical use, abciximab (ReoPro), is a human-murine chimeric Fab fragment of a monoclonal antibody that targets the β_3 subunit of $\alpha_{IIb}\beta_3$ and therefore also reacts with another integrin that shares the β_3 subunit, $\alpha_V\beta_3$. Although $\alpha_{IIb}\beta_3$ expression is restricted to megakaryocytes and platelets, $\alpha_V\beta_3$ is expressed on platelets; at low levels; and in cells of the vascular wall, including endothelial cells and fibroblasts.[63] The clinical relevance of this cross-reactivity is unclear. Abciximab administered intravenously as a standard 0.25 mg/kg bolus blocks approximately 80% of surface $\alpha_{IIb}\beta_3$ and inhibits platelet aggregation to a similar extent, although the extent of inhibition is variable.[62] This level of blockade increases the bleeding time only mildly.[64] The bleeding time only becomes markedly prolonged when receptor blockade exceeds 90%. After the bolus dose, abciximab is infused at 0.125 g/kg/min for 12 hours. Several trials have established this as a clinically effective regimen.[62] Plasma levels of free abciximab drop rapidly after its administration, with an initial half-life of approximately 30 minutes. Most of the drug is bound to platelets. This explains why patients with thrombocytosis may require larger weight-adjusted doses of abciximab to attain a therapeutic antiplatelet effect[65] and why patients with lower platelet counts treated with the usual dose of abciximab display more profound platelet inhibition. Abciximab is not excreted in the urine and is probably metabolized by the reticuloendothelial system at the time platelets (with bound abciximab) are cleared from the circulation. The dose of abciximab does not have to be adjusted in patients with renal impairment. Although a daily platelet turnover rate of 10% would predict that no abciximab would be detected in blood after 10 days of its administration, platelet-bound abciximab has been observed up to 3 weeks after its initial administration, suggesting platelet-to-platelet redistribution of the drug or release of new platelets from megakaryocytes that had previously bound the drug. Several in vitro and in vivo studies confirm abciximab's ability to exchange between platelets.[66] Because of the low plasma levels of unbound abciximab, the drug's inhibitory effect can be rapidly reversed by platelet transfusion; and hemostasis should be normal when the concentration of infused platelets exceeds 50,000/μL, as it is in normal individuals. However, because of abciximab's ability to redistribute to the newly transfused platelets, the platelet-bound abciximab may produce a gradual inhibitory effect on the infused platelets[66]; in severe or refractory bleeding, it may be necessary to infuse a very large dose of platelets, sufficient to leave 50% of $\alpha_{IIb}\beta_3$ receptors free, a number shown to be sufficient for normal hemostasis in studies of Glanzmann thrombasthenia heterozygotes. Without platelet transfusions, platelet aggregation generally returns to baseline levels within 12 to 24 hours after discontinuing abciximab.

Eptifibatide

Eptifibatide (Integrilin) is a cyclic heptapeptide based on the Lys-Gly-Asp (KGD) sequence found in barbourin, a platelet-inhibitory disintegrin from the venom of the Southeastern Pigmy rattlesnake, *Sistrurus miliarius barbouri*.[67] Barbourin differs from other integrin-binding proteins with the Arg-Gly-Asp (RGD) canonical sequence in that the arginine is conservatively substituted by lysine, a change that renders the protein a specific inhibitor of $\alpha_{IIb}\beta_3$.[67] Eptifibatide incorporates the KGD sequence within a cyclic seven-member peptide of high potency. Eptifibatide differs pharmacokinetically from abciximab in several important ways.[62] For example, unlike abciximab, intravenous eptifibatide infusion produces high levels of unbound drug because of its lower affinity for the receptor. Platelet transfusions therefore are not a good method for acutely reversing eptifibatide's antiplatelet effect because the newly transfused platelets are rapidly inhibited. However, its short plasma half-life (≈2.5 hours) allows for rapid clearance of eptifibatide and the reversal of its antiplatelet effect when administration is discontinued. Platelet aggregation returns to normal in approximately 4 hours, with the bleeding time normalizing within 1 hour.[62]

Tirofiban

Tirofiban (Aggrastat) is a peptidomimetic agent based on the RGD sequence, with a pharmacokinetic profile similar to that of eptifibatide.[62] Tirofiban antagonizes $\alpha_{IIb}\beta_3$ and does not cross-react with $\alpha_V\beta_3$.[68] As with eptifibatide, the maximum antiplatelet effect is seen at concentrations that leave a high concentration of unbound drug in the plasma.[62] Therefore, platelet transfusions are not often effective in reversing tirofiban's antiplatelet effect. However, its half-life is even shorter than that of eptifibatide (≈2 hours), and its antiplatelet effect is reversed rapidly after discontinuation of infusion.

The major adverse effects of $\alpha_{IIb}\beta_3$ inhibitors are thrombocytopenia and bleeding complications. Up to 5% of patients receiving abciximab may experience mild thrombocytopenia (<100,000/μL), and 1% may develop profound thrombocytopenia (platelet count <20,000/μL).[69,70] The incidence of severe thrombocytopenia is lower with tirofiban and eptifibatide, being approximately 0.2%.[70-72] A decrease in the platelet count is appreciable within the first hours after administration. It is therefore essential that a platelet count be obtained 2 to 4 hours after initiating treatment. Most patients with severe thrombocytopenia respond well to platelet transfusions and their platelet counts usually recover within 5 days, although they may take more than 1 week to do so. Because patients receiving abciximab frequently also receive heparin, heparin-induced thrombocytopenia (HIT) must be excluded. Ethylenediaminetetraacetic acid (EDTA)–dependent pseudothrombocytopenia should also be considered and ruled out by examination of a blood smear for the presence of platelet aggregates. Many patients require readministration of abciximab, raising the possibility that antibodies against the drug will complicate therapy. The safety of readministration was studied systematically in the ReoPro Readministration Registry.[69] The study found that abciximab readministration has a high clinical success rate and is not associated with hypersensitivity reactions, excessive bleeding, or death, and the incidence of thrombocytopenia is no greater than that seen in patients receiving abciximab for the first time. However, thrombocytopenia tended to be profound, relatively refractory to platelet infusion, and more often delayed. It is therefore recommended that clinicians obtain a second platelet count 24 hours after the readministration of abciximab and that they maintain a high index of suspicion for the delayed development of abciximab-induced thrombocytopenia.

Bleeding complications are quite common, especially in the inguinal area, where the femoral artery has been breached during procedures. Rates of major bleeding vary between 0.7% and 5.2% in different randomized controlled studies.[71,72] Intracranial bleeding is very rare (0.09%).[72] Bleeding risk increases in patients older than 65 years of age; in patients weighing less than 50 kg; in patients taking anticoagulant, antiplatelet, or thrombolytic therapies; and in patients with inherited or acquired bleeding disorders such as hemophilia and uremia, respectively.[72,73] Assessment of the risks and appropriate selection of the patients will decrease major bleeding complications in patients using glycoprotein (GP) IIb/IIIa inhibitors.

Phosphodiesterase Inhibitors

Elevation of cAMP and cyclic guanosine monophosphate (cGMP) inhibits many pathways involving platelet activation, including shape change, $\alpha_{IIb}\beta_3$ activation, and degranulation. Phosphodiesterases (PDEs) catalyze degradation of cAMP and cGMP, thus preventing platelet inhibition. Eleven PDE isoforms have been described, and three are expressed in platelets: PDE2, PDE3, and PDE5.[74] Many PDE inhibitors have antiplatelet effects.

Nonselective Phosphodiesterase Inhibitors

These include the methylxanthines caffeine (1,3,7-trimethylxanthine), theophylline (1,3-dimethylxanthine), and pentoxifylline (3,7-dimethyl-1-(5-oxohexyl)xanthine). Caffeine, at a dosage of 250 mg orally three times a day for 1 week, was demonstrated to reduce platelet aggregation in healthy subjects.[75]

PDE3 inhibitors are anagrelide, cilostazol, and milrinone. Although anagrelide inhibits platelet aggregation in vitro, it surprisingly also inhibits megakaryocyte maturation and proliferation and causes thrombocytopenia in humans by a mechanism that is poorly understood.[76] Anagrelide is used to treat essential thrombocytemia.[77]

Cilostazol is a cyclic nucleotide PDE inhibitor with both platelet inhibitory and vasodilatory effects; its current clinical use for peripheral vascular disease in the United States was preceded by its use in Japan and other Asian countries. In addition to selectively inhibiting PDE, cilostazol also inhibits adenine nucleotide uptake, a property not shared with other PDE inhibitors that further enhances its antiplatelet activity.[78]

Milrinone inhibits platelet aggregation and shape change. The drug is used for congestive heart failure.

PDE5 Inhibitors

Dipyridamole has several biologic effects, including PDE inhibition, targeting the PDE5 isoform that degrades cGMP.[79] It also enhances the release and prevents the breakdown of prostaglandin I_2 (prostacyclin).[80] Primarily used for prevention of stroke, its usefulness was demonstrated by a meta-analysis of recent randomized trials showing that the combination of dipyridamole (particularly the modified release form) and low-dose aspirin was more effective than aspirin alone in secondary prevention of vascular events after transient ischemic attack or stroke.[81] Dipyridamole has been associated with a significantly increased risk of GI bleeding when used either as a single agent or in combination with aspirin.[82]

Recently, inhibitors of PDE5 have become popular in the treatment of erectile dysfunction.[83] PDE5 is expressed in platelets, and its inhibition results in increases in the level of platelet cGMP, an effect similar to the effect of the well-known inhibitor of platelet function, nitric oxide. One study examined the activation response of platelets drawn from patients taking sildenafil (Viagra) when stimulated with either ADP or low-dose thrombin. The results showed significantly reduced activation to ADP in sildenafil-treated platelets, suggesting that the drug impairs selected pathways of platelet function in vivo. Several reports of sildenafil-associated bleeding have appeared, including epistaxis,[84,85] hemorrhoidal bleeding,[86] spontaneous intracranial hemorrhage,[87] and acute variceal bleeding.[88]

Adenyl Cyclase Stimulators or Prostacyclin Analogues

Epoprostenol (the synthetic salt of prostacyclin), prostacyclin (iloprost), and an orally active stable analogue (beraprost) are prostacyclin-like agents in clinical use. Despite the potent inhibition of platelet aggregation by prostacyclin in vitro, the effects on the bleeding time are minimal and inconsistent. These drugs are used for pulmonary arterial hypertension and peripheral artery disease.[89]

PERIOPERATIVE MANAGEMENT OF PATIENTS RECEIVING ANTIPLATELET THERAPY

The widespread use of antiplatelet therapies in patients with arterial disease or at risk for developing arterial diseases increases the risk of both spontaneous bleeding and surgical and traumatic bleeding.[90,91] For example, several studies have demonstrated that aspirin increases blood loss and transfusions in patients undergoing surgery.[64,91-95] Discontinuation of antiplatelet therapy before surgery has to be balanced against the increased risk of arterial thrombosis, as was seen in patients who had recent coronary stent implantation.[96] Optimal management of surgical bleeding risk in patients on platelet inhibitors thus requires consideration of patient features (both thrombosis risk and comorbidities), the reasons for antiplatelet therapy, the dose and the modality of drugs (single, dual, or triple antiplatelet therapy), individual responses to the drugs (noncompliance, the presence of aspirin or clopidogrel resistance), and the type of surgery to be performed.

Patients on antiplatelet therapy can be divided into two groups according to the risk of thrombotic complications. Low-risk patients include those receiving single antiplatelet therapy (usually low-dose aspirin) for primary prophylaxis of arterial disease. The high-risk group includes patients having had a recent (within 3-6 months) myocardial infarction, stroke, or peripheral arterial thrombosis and patients who have had recent implantation of a coronary stent.[95] Patients with coronary stents need special attention and may be considered to be at very high risk for thrombosis and death. Endothelization of bare metal stents requires 4 to 6 weeks but could take up to 1 year for drug-eluting stents. Dual therapy with aspirin plus clopidogrel is recommended for 12 months.[64,97,98] Other high-risk patients are patients receiving combined antiplatelet therapy, such as aspirin plus dipyridamole for stroke prevention and aspirin plus cilostazole for peripheral arterial disease. Approximately 6% to 8% of patients taking combined antiplatelet therapy for coronary artery disease also receive oral anticoagulants due to cardiac rhythm or valve problems.[91,97] For patients taking aspirin and undergoing minor dental, dermatologic, or cataract surgery, current guidelines recommend that aspirin not be stopped during these procedures because bleeding can be readily controlled with local hemostatic agents.[64,92,97] There are only limited data for patients taking clopidogrel in such situations; the decision as to whether to discontinue the drug should be made according to the individual patient's risks. In major surgical procedures such as cranial, spinal, abdominal, urological, major orthopedic or thoracic surgical operations, or posterior chamber eye surgery, antiplatelet therapy should be stopped according the patient's thrombosis risk. Aspirin and clopidogrel irreversibly inhibit platelets; restoration of normal platelet hemostasis thus requires a few days after cessation of the drug. For *patients at low risk for cardiovascular events,* guidelines published by the American College of Chest Physicians (ACCP) suggest stopping antiplatelet treatment 7 to 10 days before surgery[99]; others recommend waiting 5 to 7 days after the last dose.[64,92,97] The ACCP guidelines also suggest resuming aspirin or clopidogrel 12 to 24 hours after surgical bleeding has ceased. In patients at *moderate to high risk* for cardiovascular events (except patients with recent stents) who require noncardiac surgery or coronary artery bypass, the ACCP guidelines recommend continuing aspirin around the procedure but stopping clopidogrel at least 5 days before surgery.[64,92,97] *In patients with recent coronary stent placement,* elective surgeries should be deferred at least 6 weeks in those with bare metal stents and for at least 6 months in those with drug-eluting stents.[99] The risk of major adverse events, which are primarily cardiac, is very high (≤45%) in patients who have recent coronary stent placement.[92] This enhanced risk is not merely a consequence of stopping antiplatelet therapy. Hypoxia, hypercoagulability, and inflammatory responses caused by the operation are also associated with stent thrombosis and adverse cardiac events in these patients. If surgery is required, it is recommended that both aspirin and clopidogrel be continued.[64,91,97] If the operation is associated with a high risk of bleeding and the consequence of bleeding is likely to be dire (as in

intracranial operations), the risk of bleeding must be balanced against the risk of thrombosis during the perioperative period. Clopidogrel may be stopped for 1 week in these situations.[91,92]

In patients taking vitamin K antagonists, bridge therapy with short-acting anticoagulants may prevent perioperative thrombosis without excessive bleeding. Replacement of aspirin with unfractionated or low-molecular-weight heparin is not recommended because heparins do not protect against myocardial infarction or stent thrombosis.[64,97] Replacement of aspirin or clopidogrel with short-acting $\alpha_{IIb}\beta_3$ inhibitors beginning 5 days before the planned surgery may decrease bleeding complications while minimizing the thrombotic risks. The short half-lives of tirofiban and eptifibatide may allow use of these drugs until 4 hours before surgery.

For emergency surgeries with a high risk of bleeding, there is no time to stop antiplatelet therapy. In these cases, platelet transfusions, antifibrinolytic agents (tranexamic acid and epsilon aminocaproic acid), and desmopressin (DDAVP) may help to control excessive bleeding.[64,91,97]

Although the ACCP guidelines recommended against the routine use of platelet function assays to monitor the antiplatelet effects of aspirin and clopidogrel,[64] there is no consensus on this topic.

Other Drugs that Adversely Affect Platelet Function

Nonsteroidal Antiinflammatory Drugs

In addition to aspirin, many other drugs used for their antiinflammatory and analgesic properties can cause platelet dysfunction.[100] As with aspirin, their mechanism of action appears to be the inhibition of COX-1; but in contrast to aspirin, these agents only temporarily affect COX-1 function, inhibiting the enzyme only as long as the active drug circulates. Among these agents, therefore, only drugs such as piroxicam, which has a plasma half-life of more than 2 days,[101] affect platelets for more than a few hours. As with aspirin, the most sensitive indication of impaired platelet function is the inhibition of in vitro platelet aggregation and secretion. These agents prolong the bleeding time minimally and transiently or not at all, consistent with the bleeding time being a less sensitive measure of the aspirin-induced defect.[100] The platelet function analyzer–100 more reliably detects the defect, manifested as a prolonged clotting time with the collagen/epinephrine cartridge.[102]

Reports of bleeding correlate with the effects of these agents on platelet function, suggesting that they increase the risk for excessive bleeding less than aspirin. As with aspirin, they may increase the bleeding times in patients with severe hemophilia, but in two studies, therapeutic doses of ibuprofen had no effect on the bleeding time in 19 of 20 patients with hemophilia.[103] Therefore, the clinical approach to patients taking any drug that can inhibit COX-1 should be similar, but the reversibility of the effect of NSAIDs provides an added margin of safety when these agents are used. Because of the increased bleeding risk, these drugs should be stopped before surgery. The timing for cessation of NSAIDs is based on the half-lives of the individual drug. Indomethacin, ibuprofen, ketoprofen, and diclofenac all have short half-lives (2-6 hours), and discontinuing these drugs 1 day before surgery is sufficient. Naproxen, sulindac, diflunisal, and celecoxib have intermediate half-lives (7-15 hours) and should be stopped 2 or 3 days before surgery. Nabumetone, meloxicam, piroxicam have very long half-lives (>20 hours). The ACCP guidelines recommend discontinuing these drugs 10 days before surgery.[64] Analgesics such as acetaminophen and sodium or choline salicylate, do not inhibit platelet function and have no adverse effects on hemostasis.[103]

Cardiovascular Drugs

Administration of nitroglycerin, isosorbide dinitrate, or nitroprusside can decrease platelet aggregation and secretion in vitro, but their effects in vivo are minimal and inconsistently observed.[100] The mechanism of platelet inhibition appears to involve the production of nitric oxide from the drug, with concomitant increases in platelet cAMP and, more markedly, cGMP.[104] α-Adrenergic receptor blockers such as propranolol, metoprolol, nebivolol, and pindolol have also been shown to inhibit platelet aggregation, apparently through mechanisms independent of α-adrenergic receptor blockade.[105,106] Several of these agents have been shown to blunt platelet aggregation to ADP and collagen[107] and to decrease platelet TXA_2 production in response to agonists.[105] Blunting of serotonin uptake by platelets and inhibition of the response to serotonin have also been demonstrated. There are numerous reports of antiplatelet effects of calcium channel blockers, such as nifedipine, verapamil, and diltiazem. Most of these studies demonstrated inhibition of platelet aggregation in vitro when high concentrations (micromolar) of the drug were used with washed platelets. This effect is mainly with epinephrine as the agonist, and it does not appear to be related to inhibition of calcium ion influx. Proposed mechanisms include inhibition of epinephrine binding to α_2-adrenergic receptors, inhibition of the platelet response to TXA_2, and inhibition of serotonin-induced aggregation. In therapeutic doses, the calcium channel blockers do not prolong the bleeding time. At high concentrations, quinidine can act as an antagonist of platelet α_2-adrenergic receptors. In one report, a patient taking 800 mg of quinidine and 650 mg of aspirin daily developed melena and generalized petechiae with a normal platelet count and a bleeding time over 35 minutes.[108] In a subsequent study in two healthy volunteers, quinidine caused a mild prolongation of the bleeding time that was apparently potentiated by aspirin. Quinidine and its stereoisomer, quinine, can also impair hemostasis by inducing drug-dependent antibodies that cause thrombocytopenia.

The commonly used antihypertensive drug losartan, an angiotensin II receptor antagonist, interacts with the TXA_2 receptor and inhibits thromboxane-dependent platelet adhesion and aggregation.[109]

Antibiotics

Antibiotics can also affect platelet function.[100] Those implicated most often are the penicillins and cephalosporins, which share a β-lactam ring structure. Some of these drugs produce predictable dose- and duration-related effects on the bleeding time.[110-112] Because the effect on bleeding time is seen only in patients who are receiving large parenteral doses of antibiotics, this is a potential problem only for hospitalized patients. In a study of 74 hospitalized patients with a consistently prolonged bleeding time, the likely cause was penicillin in 39 patients (30 patients were receiving >15,000,000 U/day of penicillin G, and nine were receiving 6-8 g/day of ampicillin) and aspirin or related drugs in seven patients.[112]

The structural properties that cause some, but not all, penicillins and cephalosporins to affect platelet function are unknown. The side chain structure alters the antibacterial and pharmacologic properties of the penicillins and cephalosporins and may also determine their effects on platelet function. It is postulated that the antibiotic associates with the platelet plasma membrane via a lipophilic mechanism where it perturbs receptor–agonist interactions or signal transduction.[113] The characteristic laboratory findings are a prolonged bleeding time and abnormal platelet aggregation studies that occur after several days of high-dose parenteral therapy.[111,112] These abnormalities do not usually subside until several days after the antibiotic is discontinued.

The frequency of clinically important bleeding in patients taking β-lactam antibiotics is low and is not predicted by a prolonged bleeding time; consequently, the causal relation to antibiotic treatment is unproved.[114] For each report implicating an antibiotic as a cause of hemorrhage, many more patients receive the same antibiotics in large doses without bleeding complications.[114]

In conclusion, antibiotic-induced platelet dysfunction appears to have little clinical importance, and the potential effect on platelet function should not be a consideration when choosing antibiotics. An exception to this rule may be moxalactam. The frequency of

clinically important hemorrhagic complications with moxalactam appears to be higher than with other antibiotics.[114] This drug has been demonstrated to inhibit ADP- and collagen-induced platelet aggregation in a dose-dependent fashion and to decrease TXA_2 generation,[115] which suggests that, similar to aspirin, it acts on the thromboxane synthesis pathway. Furthermore, in contrast to most other β-lactam antibiotics, moxalactam contains a methylthiotetrazole-leaving group that has been implicated in the inhibition of synthesis of the vitamin K–dependent coagulation factors.[116] Therefore, moxalactam-induced bleeding may be caused by the combination of deficiencies in vitamin K–dependent coagulation factors and impaired platelet function.

Nitrofurantoin, an antibiotic structurally unrelated to the β-lactam antibiotics, may mildly prolong the bleeding time and impair platelet aggregation at plasma concentrations in excess of 20 μM.[117] Nitrofurantoin is not known to cause clinical bleeding.

Psychiatric Drugs

Platelets from patients taking tricyclic antidepressant drugs (imipramine, amitriptyline, nortriptyline) or phenothiazines (chlorpromazine, promethazine, trifluoperazine) may exhibit impaired in vitro aggregation and secretion responses to ADP, epinephrine, and collagen, but this effect is not associated with an increased risk for bleeding.[100] There are numerous reports of antiplatelet effects of the widely used selective serotonin reuptake inhibitors (paroxetine, sertraline, fluoxetine, citalopram), which may block the only means of platelet serotonin uptake for storage[118-122]; the effect of these drugs in decreasing platelet serotonin levels has been documented.[123,124] Prolonged bleeding times,[125] excessive bruising,[126] and defective platelet aggregation have all been noted in patients taking fluoxetine.[127] Additionally, the risk of GI bleeding is increased in patients taking serotonin reuptake inhibitors, particularly when they are combined with NSAIDs.[128] Further evidence of the antiplatelet effects of serotonin reuptake inhibitors, especially those that bind the serotonin transporter with high affinity, is a reduction in the risk of myocardial infarction with these drugs compared with other antidepressants or no drugs at all.[129]

Oncologic Drugs

Administration of mithramycin has been associated with decreased platelet aggregation, a prolonged bleeding time, and mucocutaneous bleeding.[130] Daunorubicin and bis-chloroethyl-nitrosourea can both inhibit platelet aggregation and secretion when added to platelet-rich plasma, but these effects do not appear to be clinically important.[100] Vincristine inhibits platelet aggregation by interfering with the microtubule network.[131]

Anesthetics

Although some local and general anesthetic agents have been shown to inhibit platelet functions in vitro, this effect is generally produced at high drug concentrations.[132,133] Procaine inhibits calcium and P-selectin release from platelet storage pools.[134] Dibucaine is a calpain activator, induces platelet apoptosis, and inhibits platelet functions.[135] At usual doses, halothane reversibly inhibits platelet aggregation.[136]

Plasma Expanders

Dextrans are partially hydrolyzed branched polysaccharides of glucose. Of the two preparations in clinical use, dextran 70 has an average molecular mass of 70-75 kDa and dextran 40 has an average molecular mass of 40 kDa. Both preparations are effective plasma expanders and can affect platelet function, but the high-molecular-weight molecules have a greater effect on hemostasis.[137] Dextran infusion also impairs platelet aggregation and platelet procoagulant activity and can cause a modest reduction in plasma vWF concentration. However, dextran has no effect on platelet function when added directly to platelet-rich plasma in vitro.[138] Because of its effects on platelet function, dextran was explored as an antithrombotic agent, but it is no longer used for this purpose.

Hydroxyethyl starch, known as *hetastarch,* is a synthetic glucose polymer with an average molecular weight of 450,000 (range, 10,000-1,000,000) that is also used for plasma expansion. Hetastarch use has been associated (albeit inconsistently) with abnormal platelet function, and this appears to be more evident with the higher-molecular-weight forms.[139] Similar to dextran, it can prolong the bleeding time, particularly if administered at doses higher than 20 mL/kg in a 6% solution, and predisposes to bleeding if administered simultaneously with heparin or in the presence of a preexisting hemostatic defect.[140]

Heparins and Thrombolytic Agents

Although heparin is best known for its anticoagulant effect and its association with HIT and thrombosis (see Chapters 135 and 151), it also has the potential to affect platelet function. Heparin can bind to the platelet surface,[141] cause platelet aggregation and secretion,[142] and impair vWF-dependent platelet function.[143] Heparin can also increase the bleeding time.[144] Whether these phenomena contribute to heparin-induced bleeding is unknown. The prolonged bleeding time is probably the result of inhibition of thrombin generation, analogous to the slight but significant increase in bleeding times seen in patients with hemophilia.[136]

Paradoxically, heparin is also capable of inducing the association of vWF with the GPIb complex.[145] Whether this is restricted to certain individuals or occurs only at certain heparin doses is unclear, but it raises the possibility that this mechanism may contribute to heparin-induced thrombosis.

Bleeding during therapy with plasminogen activators is predominantly caused by fibrin degradation, hypofibrinogenemia and increased levels of fibrin(ogen) degradation products, usually in the setting of structural lesions. At pharmacologic concentrations, streptokinase, urokinase, and tissue plasminogen activator (t-PA) may also impair platelet function through several potential mechanisms, all related to excessive production of plasmin.[146] First, high levels of fibrin(ogen) degradation products and low levels of fibrinogen may impair platelet aggregation. Second, the binding of plasminogen to the platelet surface may facilitate its conversion to plasmin.[147] Plasmin can degrade GPIbα (thereby impairing the interaction of the platelet with vWF[148]) and fibrinogen (thereby dispersing platelet aggregates).[149] Third, plasmin can inhibit platelet aggregation by blocking the release of arachidonic acid from platelet membranes, thereby limiting TXA_2 production.[150] The clinical importance of these observations is unknown.

In addition to decreasing platelet function, plasmin has been shown to directly activate platelets,[151-154] an effect that may contribute to vessel reocclusion after t-PA treatment for myocardial infarction.[155] Platelet activation is the result of plasmin-mediated cleavage of protease-activated receptors (PAR), particularly PAR4.[156]

Miscellaneous

The statins, which inhibit 3-hydroxy-3-methylglutaryl coenzyme A reductase, are widely used in patients with dyslipidemia.[157] These agents reduce the risk of cardiovascular events through a variety of mechanisms, including reducing the risk of atherothrombosis. Among its antithrombotic effects are decreases in platelet reactivity, brought about by its beneficial effects on endothelial cells, with increased production of nitric oxide and prostacyclin, and by direct effects on platelets.[158] Membrane cholesterol content, which is lowered by the statins, has been correlated with platelet reactivity,[159,160] with studies demonstrating that the content of cholesterol in platelet membranes correlates with localization of important adhesive and agonist receptors within membrane microdomains known as lipid rafts.[161,162]

Statins, in addition to lowering plasma and membrane cholesterol levels, also reduce the activity of stimulatory signaling pathways involving the small guanyl triphosphate (GTP)–binding proteins Ras, Rho, and Rac, which require posttranslational prenylation to be targeted to cell membranes. Statins inhibit protein prenylation.[163] No bleeding complications have been associated with statin use, but a substudy of the Platelet Receptor in Ischemic Syndrome Management (PRISM) trial showed that their sudden withdrawal in the setting of acute coronary syndrome was associated with an increased cardiac risk compared with that in patients who continued to receive statins (relative risk, 2.93) or never received statins.[164] This increase in cardiac events was partially attributed to increased platelet reactivity mediated through direct and indirect mechanisms. A recent meta-analysis found no correlation between statin therapy and increased intracranial hemorrhage.[165]

Clofibrate, another lipid-lowering drug, diminishes platelet responsiveness to ADP, collagen, and epinephrine when given to patients with type II hyperbetalipoproteinemia and can diminish the responsiveness of normal platelets to ADP and epinephrine in vitro.[100]

Cocaine accounts for more drug-related visits to emergency departments in the United States than any other drug except alcohol. Its use is associated with a large increase in the incidence of myocardial infarction in individuals who are otherwise at low risk, and it has been hypothesized that cocaine-induced platelet aggregation is a major contributor to this risk.[166] In vitro, however, cocaine inhibits platelet aggregation in response to several agonists and dissociates preformed aggregates.[167]

Ketanserin, which has been studied for its potential to prevent atherosclerotic complications, decreases platelet aggregation in response to serotonin. Antihistamines, some radiographic contrast agents, and immunosuppressive drugs can also impair platelet aggregation. The mechanisms responsible for these effects are unknown.

Foods and Food Additives

Certain foods and food additives can have important effects on platelet function, particularly when consumed in large quantities. In a classic study published in 1979, Dyerberg and Bang[168] reported that Greenland Eskimos on traditional diets had markedly prolonged bleeding times compared with gender- and age-matched Danish control subjects (mean, 8.1 min vs. 4.8 min, respectively), and they correlated this finding with an impaired secondary wave of platelet aggregation to ADP and collagen and high plasma levels of ω-3 fatty acids. The proposed mechanisms by which ω-3 fatty acids (eicosapentaenoic acid, C20:5ω-3; and docosahexaenoic acid, C22:6ω-3) interfere with platelet function is through competition with arachidonic acid for the 2-acyl position of membrane phospholipids or access to COX-1.[169,170] ω-3 Fatty acids not only reduce TXA_2 synthesis in response to platelet agonist stimulation by competing with the substrate arachidonic acid but also by producing inhibitory eicosanoids. The latter mechanism was substantiated in the original study of Eskimos by the demonstration that administration of aspirin decreased the bleeding time in all subjects tested but not to normal levels.[168] Additionally, ω-3 fatty acids may increase the production of antiaggregatory prostaglandins by cells in the vessel wall.[168]

Ethanol, one of the most commonly and excessively ingested substances in the world, acts synergistically with aspirin to prolong the bleeding time.[171] In addition, ethanol acts cooperatively with agents that block binding of fibrinogen to $\alpha_{IIb}\beta_3$ to further reduce platelet aggregation in response to several agonists, an effect not solely the result of reduced TXA_2 generation.[172] Ethanol may also impair collagen-induced platelet aggregation, secretion, arachidonate mobilization, and TXA_2 formation, but it did not inhibit platelet adhesion to deendothelialized rabbit aortae.[173]

Other food components or additives may also affect platelet function and increase the risk of minor bleeding. Easy bruising after eating Chinese food has been attributed to a platelet inhibitory effect of black tree fungus.[174] A component of onion extract can inhibit platelet arachidonic acid metabolism.[175] Ajoene, a component of garlic, is an inhibitor of fibrinogen binding to platelets and platelet aggregation.[176] Extracts from frequently consumed spices—cumin, turmeric, and clove—can decrease platelet thromboxane production and inhibit platelet aggregation.[177]

It can be concluded that platelets are sensitive to a variety of therapeutic and dietary compounds.[100] However, an increased risk for clinically important bleeding has been demonstrated only for aspirin and agents specifically designed to inhibit platelet function. Reports of increased bleeding with all other agents must be viewed with caution. Despite this qualification, it is prudent for clinicians to have a thorough understanding of the antiplatelet effects of prescribed drugs and to always consider the potential impacts of drug- or diet-induced platelet dysfunction, particularly in patients with coexisting hemostatic defects.

CLONAL DISORDERS

Hematological Clonal Disorders

Myeloproliferative Neoplasms

According to the 2008 World Health Organization classification, the Philadelphia chromosome–negative myeloproliferative neoplasms (MPNs) include polycythemia vera (PV), essential thrombocythemia (ET), primary myelofibrosis (PMF), chronic neutrophilic leukemia, chronic eosinophilic leukemia, mast cell disease, and unclassified MPN.[178] Of these, PV, ET, and PMF are the most common MPNs and share several features. All three disorders are characterized by bone marrow hypercellularity and megakaryocytic hyperplasia, and megakaryocyte clustering. Chronic MPNs are clonal disorders, with the molecular lesion involving a hematopoietic stem cell. Thus, even when the phenotype is dominated by excessive proliferation of erythrocytes, such as in PV, the platelets are also products of the abnormal clone. In 2005, several laboratories identified an important causative mutation in MPNs, which results in a single, relatively conserved amino acid change (V617F) in the signaling protein Janus kinase 2 (JAK2).[179-183] This gain-of-function mutation is not present in the germline but is acquired in hematopoietic stem cells and increases the sensitivity of hematopoietic precursors to stimulation by erythropoietin and thrombopoietin, accounting for the increased red cell and platelet counts observed in the MPNs. Although the presence of the JAK-2 V617F mutation establishes the diagnosis of MPN and excludes secondary causes of erythrocytosis and thrombocytosis, this mutation does not discriminate among PV, ET, and PMF. It is estimated that the prevalence of the JAK-2 V617F mutation is 95% to 98% in patients with PV and 50% to 60% in those with ET or PMF (see Chapters 67-69).[184,185] After the demonstration of the importance of cell growth and proliferation pathways in MPNs, several other mutations in these pathways were described in MPN patients who are Philadelphia chromosome and JAK2 V617F negative. Mutations in exon 12 of JAK2 are associated with erythrocytosis, and are found in approximately 3% of PV patients. Mutations in MPL, the receptor for thrombopoietin, cause thrombocytosis and are found in 3% of patients with ET and 5% to 10% of those with PMF. Other mutations associated with MPNs affect TET-2, ASXL1, IDHCBL, LNK, EZH2, and IKZF1.[178,185,186]

The MPNs are characterized by varying degrees of leukocytosis or thrombocytosis; patients with PV often have a markedly elevated hematocrit. Particularly in PV and ET, thrombosis or bleeding accounts for a high percentage of the associated morbidity of the disorders, with thrombosis being the most common. Thrombosis in patients with PV and ET can involve arteries, veins, or the microcirculation, but arterial thrombosis is the most common.[187] Microcirculatory disturbances such as erythromelalgia, a syndrome of erythema and burning pain, particularly in the fingers, are more frequently seen with ET and result from platelet-rich arteriolar microthrombi that can lead to ischemia and gangrene. Bleeding in patients with PV and

ET is primarily mucocutaneous. Some bleeding episodes can in part be attributed to thrombosis, such as variceal bleeding resulting from thrombosis-induced portal hypertension.[188] However, bleeding tendencies in these patients can be worsened by aspirin, which is sometimes given to reduce the risk of thrombosis.

In the European Collaboration on Low-dose Aspirin in Polycythemia study, 633 (38.4%) of the 1638 PV patients enrolled had a history of thrombotic events. Of these, approximately three-quarters were arterial, and one-quarter were venous. Of the 164 patients who died during the study, thrombosis accounted for 41% of the deaths and bleeding for only 7%. Excessive bleeding, particularly with surgery, was particularly common in uncontrolled PV patients with an increased whole-blood viscosity and high hematocrit.[189]

The rates of thrombotic and hemorrhagic complications in ET have been studied in 21 retrospective cohort trials, reviewed by Barbui and colleagues.[188] At the time of diagnosis, the rates of thrombosis ranged from 9% to 84%, but rates of hemorrhage ranged from 3.9% to 63%. As in patients with PV, age older than 60 years and a history of prior thrombosis predicted the risk of recurrent thrombosis.[190]

Several intrinsic platelet function defects have been associated with the MPNs, but their clinical importance is uncertain. These may result, at least in part, from an increased sensitivity of the platelets to activation, a potential consequence of the JAK2 gain-of-function mutation. For example, a study demonstrated an increased risk of thrombosis in patients with chronic MPD when the mutant kinase was detected in platelets or in platelets and granulocytes.[191] Likewise, the JAK2 mutation in platelets correlated with increased platelet expression of tissue factor and P-selectin, decreased expression of CD41 and CD42b, and increased quantities of platelet–neutrophil aggregates, all indicators of a hyperreactive platelet phenotype.[192] Panova-Noeva et al[193] evaluated the platelets from 140 patients with MPN (80 ET, 60 PV) for global procoagulant potential by measuring thrombin generation and expression of tissue factor and P-selectin on the platelet surface. They found that patients with the JAK2 V617F mutation had the highest values for thrombin generation and platelet tissue factor and P-selectin expression. These findings correlated with JAK2 V617F allele burden.[193]

The platelets of patients with MPNs can show various morphologic abnormalities, including variations in size and shape, as well as reduced numbers of secretory granules. Platelet survival may be decreased in ET. The most common platelet abnormality is decreased aggregation and secretion in response to agonists, particularly epinephrine, ADP, and collagen.[194] These abnormalities are not simply the result of the high platelet count because patients with reactive thrombocytosis have functionally normal platelets.[195] In what may appear to be a paradox, some patients demonstrate spontaneous in vitro platelet aggregation in platelet-rich plasma. The significance of this phenomenon is unknown because it can also be seen in normal individuals. Decreased platelet aggregation or secretion and decreased procoagulant activity may be caused by decreased (1) agonist-induced release of arachidonic acid from membrane phospholipids, (2) conversion of arachidonic acid to prostaglandin endoperoxides or lipoxygenase products, (3) platelet responsiveness to TXA_2, (4) dense-granule or α-granule contents, or (5) α_2-adrenergic receptors. Some of the described abnormalities may also be a consequence of platelet activation in vivo or ex vivo during platelet preparation.

Specific platelet membrane abnormalities have also been reported, including deficiencies of: glycoproteins Ib and IX, causing an acquired form of the Bernard-Soulier syndrome[196]; receptors for prostaglandin D_2[197]; c-*MPL* receptors[198]; and an increased number of Fc receptors.[199] Because MPDs are clonal in origin, the abnormal platelets may arise from a clone of abnormal megakaryocytes.[200] Alternatively, the findings may be the result of platelet hyperreactivity and previous activation.[192] It is important to emphasize several features about the platelet function defects reported in MPNs. First, no defect has consistently predicted the risk for bleeding or thrombosis. Second, no defect is unique to, and therefore predictive of, a particular MPN. Third, their relative frequency varies widely. Therefore, the clinical importance of the abnormalities of platelet function in MPNs is unknown.

The bleeding time is prolonged in a small percentage of patients with MPNs, but bleeding complications can occur even in patients with normal bleeding times. Bleeding problems are mostly associated with the administration of antiplatelet or cytoreductive drugs. Acquired von Willebrand syndrome may also cause mucocutaneous bleeding in patients with extreme thrombocytosis or may complicate surgical interventions in nonbleeding patients. In acquired von Willebrand syndrome, the largest multimers of vWF are absent, presumably as a consequence of their adsorption to binding sites on the elevated numbers of platelets.[201-205] In a prospective study of MPN patients, the incidence of acquired von Willebrand syndrome was 11%.[206] Although increased adsorption of plasma vWF multimers by platelets is the cause of the syndrome and decreased vWF:RCo/Ag or vWF:collagen binding/Ag ratio was found in patients with extreme thrombocytosis,[205] acquired von Willebrand syndrome has also been described in patients with platelet counts between 120 and 135 $\times$ 10^9/μL.[206] The diagnostic criteria for acquired von Willebrand syndrome are the same as those for hereditary von Willebrand disease.

Routine plasma coagulation tests, such as the PT and aPTT, may be falsely prolonged in MPN patients if the red blood cell mass is increased. Because the plasma volume in these patients is reduced, it is important to adjust the citrate concentration in the tubes used to collect the blood for coagulation testing.

Management

In MPN patients, risk stratification systems are used to predict complications and survival. Two large studies have established age and a history of thrombosis as important risk factors for thrombosis in PV and ET patients.[207,208] Patients who are younger than 60 years of age and have no history of thrombosis are classified as "low risk," and those with a history of thrombosis or an age older than 60 years are classified as "high risk" for thrombosis. In low-risk ET or PV patients, the presence of extreme thrombocytosis (>1000 $\times$ 10^9 platelets/L) is associated with a higher risk for bleeding.[185,193,209] Besides age and history of thrombosis, other factors associated with shortened survival in patients with PV and ET include leukocytosis, the presence of the JAK2 mutation, and anemia. The International Prognostic Scoring System (IPSS) uses five criteria for risk assessment in PMF: age older than 65 years, the presence of constitutional symptoms, anemia (hemoglobin <10 g/dL), leukocytosis (>25 $\times$ 10^9/L), and the percentage of circulating blast cells (>%1). Recently, a "Dynamic IPSS" (DIPSS) score was introduced, which also considers transfusion requirements, thrombocytopenia (<100 $\times$ 10^9/L), and karyotype abnormalities as risk factors. According to the DIPSS, PMF patients are classified as low risk (no risk factors), intermediate risk (1-3 risk factors), and high risk (>4 risk factors); the higher the risk, the shorter the survival time in PMF patients.[210]

The main goals of the therapy are to decrease peripheral cell counts, restore hemostasis, and prevent thrombosis or bleeding. Low-risk ET patients are treated with low-dose aspirin; hydroxyurea should be added for high-risk ET-patients. Published guidelines recommend that all patients with PV be phlebotomized to maintain the hematocrit below 45%.[211] In low-risk PV patients, phlebotomy and low-dose aspirin therapy are used. Hydroxyurea is added for high-risk PV patients. For PV and ET, patients who are intolerant of or reluctant to use hydroxyurea, potential alternatives include α-interferon, anagrelide, and busulphan. Although recent studies suggested that pegylated α-interferon produces high rates of both hematologic and molecular responses with low toxicity in patients with ET and PV,[212,213] side effects were more common than with hydroxyurea (affecting 96% of the patients) and resulted in discontinuation of therapy in 22% of the patients.

One study compared hydroxyurea plus aspirin with anagrelide plus aspirin for the prevention of the thrombotic complications in ET patients.[214] Anagrelide was originally developed as a platelet inhibitor but was found to lower platelet counts by inhibiting the proliferation and differentiation of megakaryocytes.[215-217] Anagrelide is more expensive than hydroxyurea. Both regimens achieved good long-term control of platelet counts, but patients in the anagrelide group were

much more likely to experience both thrombotic and hemorrhagic complications and to progress to myelofibrosis. Inexplicably, those in the anagrelide group experienced more venous thrombosis. The mortality rate was similar in the two treatment groups. This study reinforces the recommendation that hydroxyurea and aspirin should be the first-line therapy for high-risk patients, on the basis of efficacy, safety, and cost. Low-risk PMF patients are treated according to signs and symptoms; hydroxyurea is useful for treatment of symptomatic splenomegaly, androgens or thalidomide for anemia, and aspirin for thrombocytosis. Because of their poor prognosis, patients with more than two risk factors should be treated aggressively with hematopoietic stem cell transplant. Recently, ruxolitinib, a JAK inhibitor, was approved for the treatment of intermediate- and high-risk PMF patients.

Patients with thrombocytosis should be evaluated for acquired von Willebrand disease. In those with low (<30%) ristocetin cofactor activity, aspirin or other antiplatelet agents should be avoided because of the bleeding risk. In these patients, cytoreductive therapy is recommended to treat bleeding symptoms. Because cytoreductive therapy requires days or weeks to lower the blood counts, additional interventions should be used in patients with active bleeding. DDAVP was only effective in 21% of these patients because of tachyphylaxis or reduced vWF storage in the endothelium.[205] High-dose vWF concentrates and factor VIIa may be useful in MPN patients with severe bleeding. Local therapies should be considered, such as anti-ulcer therapy for active peptic ulcers, antifibrinolytic agents, and laser coagulation for nasal bleeding.

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria (PNH) is another clonal disorder that involves all blood cells. The hematopoietic stems cells and their progeny are defective in the synthesis of the glycosylphosphatidylinositol attachments required for some membrane proteins, leading to a defect in all glycosylphosphatidylinositol-linked proteins on blood cells,[218] including platelets.[219] Thrombosis is a leading cause of mortality in PNH, affecting at least half of these patients and preferentially targeting the hepatic veins.[75] Several mechanisms have been proposed to explain this association, but it is unclear whether platelets play an important role.[220] The platelet function abnormalities described in PNH range from hypersensitivity to agonists to dysfunction. One study showed platelets to be hypersensitive to epinephrine, ADP, and collagen, as judged by their abilities to aggregate and to release ^{14}C serotonin.[221] The total release of nucleotides was also markedly increased over normal with all aggregating agents. By contrast, another study examining platelets from PNH patients showed them to be profoundly hyporeactive, as measured by defective clot formation, adhesion, and aggregation.[222] This finding was interpreted as being a consequence of chronic overstimulation of the platelets while they circulate.

Platelet activation and increased platelet microparticle formation have also been demonstrated in PNH patients.[221,223] Nevertheless, a strong correlation exists between thrombosis and the number of circulating abnormal neutrophil clones.[224] It is likely that the number of abnormal granulocyte clones reflects the number of abnormal platelet clones.[225] Warfarin prophylaxis in patients with high numbers of abnormal clones significantly reduces the thrombotic risk and carries minimal bleeding risk in patients who are not thrombocytopenic. In an open-label study of eculizumab, a humanized monoclonal antibody against human complement C5 that prevents assembly of the membrane attack complex on the cell surface, there was more than a 10-fold reduction in thromboembolic events in treated patients compared with untreated patients.[226] Eculizumab reduced arterial and venous thrombotic episodes even in those taking antithrombotic medications. These encouraging results may herald a new era of therapy for PNH patients because eculizumab has also been shown to decrease transfusion requirements, reduce fatigue, and improve general well-being.[227] The major limitation to this therapy is its high cost.

Paraproteinemias

Although thrombotic complications can occur in patients with dysproteinemias because of hyperviscosity, bleeding complications also are seen. Platelet dysfunction is observed in approximately one-third of patients with immunoglobulin A (IgA) myeloma or Waldenström macroglobulinemia, in 15% of patients with IgG myeloma, and occasionally in patients with benign monoclonal gammopathy.[228,229] Additional hemostatic problems in these patients can be caused by the hyperviscosity syndrome,[230] a heparin-like coagulation inhibitor,[231] acquired von Willebrand syndrome,[205] or complications of amyloidosis (e.g., acquired factor X deficiency[232] or enhanced fibrinolysis[233]). Patients may have markedly abnormal results on laboratory tests (e.g., a prolonged thrombin time) with no evidence of clinical bleeding.[228]

Abnormalities of platelet function correlate with the concentration of the plasma paraprotein. Myeloma proteins can inhibit all platelet functions (aggregation, secretion, procoagulant activity, and clot retraction), and normal platelets can acquire these defects when incubated with the purified monoclonal immunoglobulin.[234] In some cases, specific interactions of the monoclonal protein have been described. One IgA myeloma protein inhibited the ability of a suspension of aortic connective tissue to aggregate normal platelets.[235] The bleeding time and bleeding symptoms of the patient from whom this paraprotein was isolated were corrected when the IgA myeloma protein was removed by plasmapheresis. One patient had a fatal hemorrhage from an IgG1κ paraprotein that bound GPIIIa (β_3 integrin) and inhibited platelet aggregation.[236] A number of reports have described acquired von Willebrand disease in patients with myeloma, benign monoclonal gammopathy, or chronic lymphocytic leukemia.[237] In some patients, the plasma concentration of vWF was decreased; in others, the larger multimers were deficient. The myeloma protein may interact with vWF and accelerate its clearance from plasma or interfere with its binding to platelet GPIb.

Easy bruising, epistaxis, periorbital purpura (in patients with amyloidosis), and GI hemorrhage are the most common bleeding symptoms associated with the paraproteinemias. Because bleeding appears to be related to high plasma paraprotein concentrations,[238] chemotherapy for the underlying plasma cell neoplasm should be given to effect a longer lasting reduction of the paraprotein. In emergency situations, plasmapheresis should be performed expeditiously; the effectiveness of this therapy can be evaluated by amelioration of bleeding symptoms. Intravenous immunoglobulin (IVIG) infusions are effective in controlling bleeding symptoms in patients with plasma cell dyscrasias and acquired von Willebrand disease. IVIG may produce a clinical and laboratory response in 12 to 72 hours, and the effect usually persists for 1 to 3 weeks. In patients with severe bleeding, IVIG can be combined with plasmapheresis, DDVAP, and infusions of vWF concentrates or factor VIIa.[205,206,229,237]

LEUKEMIAS AND MYELODYSPLASTIC SYNDROMES

Bleeding in patients with the leukemias and myelodysplastic syndromes (MDS) is almost always caused by thrombocytopenia, but abnormalities of platelet function have also been described. In acute myeloid leukemia and its variants, platelets may be larger than normal, abnormally shaped, and vary in their granule numbers. Abnormal platelet structure and function have been described, especially in association with acute megakaryoblastic leukemia (FAB M7),[239,240] with one study describing three patients with decreased aggregation to collagen, ADP, epinephrine, and the thromboxane analogue U46619, along with a decreased platelet serotonin content.[241] Platelet abnormalities can also be found in the MDS, with defective aggregation and glass bead retention most often associated with hypolobulated megakaryocytes and the 5q$^-$ syndrome.[242] Abnormal platelet function has also been described in association with B-cell malignancies, such as hairy cell leukemia, which can persist after splenectomy,[243] and with chronic lymphocytic leukemia,[244] in which the platelets exhibit reduced responses to glycoprotein VI agonists, such as collagen and convulxin.

SOLID TUMORS

Bleeding complications in patients with cancer are related to decreased platelet production due to bone marrow infiltration, the myelosuppressive effects of chemotherapy and radiotherapy, sepsis, disseminated intravascular coagulopathy, microangiopathic hemolytic anemia; drug-induced thrombocytopenia; immune thrombocytopenia or hypersplenism. Although several defects of platelet functions have been described in cancer patients, none is specific.[245]

SYSTEMIC METABOLIC DISORDERS

End-Stage Renal Disease

The pathogenesis of the hemorrhagic diathesis in patients with end-stage renal disease (ESRD) is complex. Factors such as platelet function abnormalities caused by uremic toxins, anemia, hemodialysis procedures (both the artificial circulation and the use of anticoagulation), and decreased drug clearance may impair hemostasis.

The recognition of severe hemorrhage as a distinct complication of renal failure is generally attributed to Reisman's description in 1907 of two patients with Bright disease who had severe and generalized bleeding.[246] Reisman proposed that the cause was "a toxin analogous to the hemorrhagins of snake venom." However, the bleeding in Reisman's patients may have reflected any number of other associated conditions.[246] Others observed a "tendency to hemorrhage" in patients with chronic glomerulonephritis in the predialysis era, and the descriptions of epistaxis and menometrorrhagia[247] suggested a primary platelet abnormality. Nevertheless, in the era before dialysis, death in patients with chronic renal failure occurred primarily from hyperkalemia and pulmonary edema.[248] After dialysis became an established treatment, the major causes of death were infection and the underlying cause of the renal failure. Hemorrhage caused 6 of 100 deaths in one series, but additional factors could have contributed in each case.[248] The current prognosis for patients with ESRD is excellent, with a significant proportion surviving past 10 years and some reported to survive up to 3 decades on hemodialysis.[249] Bleeding problems were not mentioned in this discussion, and bleeding was not considered in reviews published in the past 25 years on the clinical course and management of patients with chronic renal failure. However, bleeding and thrombosis in patients with chronic uremia continue to be discussed.[250]

A more objective indication of the rarity of a significant bleeding diathesis in patients with renal failure is the extensive experience with percutaneous renal biopsy. In a study of 1000 consecutive percutaneous renal biopsies performed at the Mayo Clinic, 69 patients had hematuria, which cleared within 2 days in 50 patients.[251] Hypertension was a more significant factor than the bleeding time in predicting the occurrence of this complication.[251] Another study of 183 consecutively performed renal biopsies reported three episodes of hemorrhage that required surgical intervention; all were the results of needle lacerations of the kidney or spleen.[252] In an analysis of 5120 renal biopsies performed at 15 institutions, there were no deaths, and severe bleeding complications appeared to be related to anomalous vessels, heparin anticoagulation, or the presence of amyloid in the kidney.[253] Reports of bleeding with other invasive procedures in patients with chronic renal disease are rare, but they suggest that bleeding complications are uncommon after abdominal surgery, liver and bone marrow biopsies, and tooth extractions.[254]

By contrast, GI tract hemorrhage is a common complication and frequent cause of death in patients with acute renal failure, and patients with chronic renal failure account for a significant proportion of patients undergoing endoscopy for upper GI bleeding.[255] Experimental data suggest that chronic uremia renders the gastric mucosa susceptible to acid injury.[256] More than 90% of patients with renal failure and GI bleeding have an anatomic diagnosis at endoscopy: Angiodysplasia is most common, but peptic lesions (gastric or duodenal ulcer, erosive esophagitis, gastritis, or duodenitis) also are frequent findings.[255] Rectal ulcers can also cause sudden, massive lower GI hemorrhage.

These observations suggest that serious, spontaneous hemorrhage is uncommon in patients with chronic renal failure. Nevertheless, platelet dysfunction is believed to constitute the primary hemostatic abnormality in uremia,[257] consistent with the common findings of easy bruising, epistaxis, gingival bleeding, and prolonged bleeding after venipuncture or trauma in patients with uremia. Descriptions of bleeding in uremia have often focused on the laboratory phenomena of abnormal platelet aggregation or a prolonged bleeding time rather than actual hemorrhagic episodes in patients.[250] As with the drug-induced disorders of platelet function discussed earlier, in uremia abnormal platelet function on laboratory tests is far more common than clinically important bleeding. Thus, laboratory evaluation of platelet function may not be a good predictor of the risk of hemorrhage.

Platelet aggregation studies are frequently abnormal in uremic patients, but these abnormalities do not correlate with the severity of the renal failure or with the occurrence of bleeding.[258] The bleeding time may also be prolonged in uremia and does not necessarily correlate with the severity of the renal failure.[258] Furthermore, controversy exists as to whether the bleeding time is a useful predictor of risk for clinically important bleeding.[259,260] One study found no difference in bleeding complications whether or not a bleeding time was performed before renal biopsy.[261]

Anemia, which does correlate with the severity of renal failure, is an independent cause of a prolonged bleeding time.[262-265] The relationship of the hematocrit to the bleeding time was first discerned in 1910 by Duke, who found that the bleeding time in thrombocytopenic patients was corrected by transfusion of fresh whole blood, but when thrombocytopenia recurred, the bleeding time was not as prolonged in the presence of a higher hematocrit.[266] Furthermore, it has been noted that bleeding times can be prolonged with severe anemia caused by deficiency of vitamin B_{12} or iron and can be corrected with red blood cell transfusions.[262] Therefore, severely anemic patients with chronic renal failure would be expected to have prolonged bleeding times. The relationship of the bleeding time to hematocrit in uremic patients has been confirmed by its correction with the transfusion of red blood cells and by treatment with erythropoietin.[264,267] There was a suggestion that bleeding symptoms also improved with correction of the anemia. It is believed that the association between anemia and a prolonged bleeding time reflects the tendency of red blood cells to displace the less dense platelets to the periphery of the cylindrical blood vessel, where the platelets are poised to survey the vascular wall for defects.[268]

In contrast to the studies of platelet function performed to understand the possible increased risk for bleeding in patients with chronic renal failure, the coagulation and fibrinolytic systems have been interrogated to understand the increased risk for thrombotic complications, a major cause of mortality.[250] Although the data are inconsistent, markers of increased activation coagulation are often seen in patients with uremia, suggesting the presence of a prothrombotic state.[250,269]

Even though the anemia of renal failure appears to be the major cause of the prolonged bleeding time, there is also evidence of abnormal platelet function. Platelet aggregation abnormalities persist when the hematocrit is normalized by red blood cell transfusion[263,264] or erythropoietin treatment.[270] The defects appear to result from intrinsic defects of the platelets and from substances in the plasma capable of inhibiting the function of normal platelets. Deficiencies in the number of GPIb complexes in uremic platelets have been reported, the number inversely correlating with the creatinine level.[271] Consistent with this finding, another study demonstrated that defective ristocetin-induced platelet aggregation of uremic platelet-rich plasma was not corrected by resuspending the platelets in normal platelet-poor plasma. Likewise, uremic platelets suspended in normal plasma were defective in their adhesion to deendothelialized rabbit vessels at high shear, a test of the competency of the interaction between GPIb and vWF.[272] Conversely, the same study demonstrated that plasma factors also influence platelet function by showing that normal

platelets suspended in uremic plasma acquired an adhesion defect possibly related to an abnormal interaction of vWF with the subendothelium. This led to the suggestion that vWF may be abnormal in uremia. Two studies have demonstrated normal to elevated vWF antigen and activity (measured as ristocetin cofactor activity) in uremic patients but decreased levels of the largest, most hemostatically active multimers,[273,274] reflected in one study as a decreased ratio of activity to antigen level compared with the vWF from normal subjects.[273] Taken together, the various studies consistently indicate that the first step of platelet adhesion at sites of vessel wall injury is abnormal, a defect that could be clinically significant if coupled with other defects of platelet function.

The platelets of uremic patients frequently exhibit reduced fibrinogen binding, aggregation, and secretion in response to a wide variety of agonists. This abnormality may persist when the platelets are removed from uremic plasma, and in some studies, uremic plasma has induced these defects in normal platelets. Uremic platelets may also exhibit a reduction in several of the biochemical responses necessary for aggregation and secretion, including the rise in cytoplasmic calcium ion concentration, release of arachidonic acid from membrane phospholipids, conversion of arachidonic acid to TXA_2, and dense-granule and α-granule secretion. Abnormal cytoskeletal assembly and deficient tyrosine phosphorylation have also been noted in uremic platelets, abnormalities only partially corrected by dialysis.[275]

The accumulation of dialyzable platelet-inhibitory substances in the plasma of uremic patients has long been recognized. The ability of uremic plasma to inhibit platelet function was demonstrated by Horowitz and colleagues,[276] who showed reduced ADP-induced platelet aggregation and a prolonged Stypven clotting time, a measure of platelet procoagulant activity. This activity, previously called *platelet factor 3,* is vital for the support of coagulation factor complex assembly on the platelet surface and requires externalization of the anionic phospholipid phosphatidylserine. One uremic substance with platelet inhibitory properties described by Horowitz and coworkers[277] was guanidinosuccinic acid, which accumulates in uremic plasma as an alternative byproduct of L-arginine metabolism,[260] a consequence of the inhibitory effect of high urea levels on enzymes of the urea cycle. Similar to L-arginine, guanidinosuccinic acid is a precursor of nitric oxide, which is produced in increased quantities in the endothelial cells and platelets of uremic patients and experimental animals.[260] Consistent with an important role for nitric oxide in uremia, infusion of the nitric oxide synthesis inhibitor monomethyl L-arginine reduced the bleeding time in uremic rats.[278] Furthermore, suppression of nitric oxide production appears to correlate with the benefit of conjugated estrogens in improving the bleeding time in uremia.[279] Increased expression of vascular prostacyclin has also been described in uremic rats, a factor that would further depress in vivo platelet function.[280]

Dialysis itself may be associated with alterations in platelet function. For example, hemodialysis may cause transient increases in the bleeding time and reduced responsiveness of platelet to agonists in vitro,[281] and chronic hemodialysis and peritoneal dialysis are associated with an increase in reticulated platelets, suggesting accelerated platelet turnover.[282] Of the two forms of dialysis, hemodialysis appears to have the greatest effect on platelet function, with one study noting abnormal cytoskeletal assembly and defective tyrosine phosphorylation to thrombin stimulation in the platelets of patients on hemodialysis, parameters that returned almost to normal with the institution of ambulatory peritoneal dialysis.[275] The cause of the defect associated with hemodialysis is likely to be the chronic low-level platelet activation associated with the procedure. In particular, polymerization and depolymerization of actin, release of granule proteins and their binding to the platelet surface, and shedding of membrane proteins may render the platelets relatively refractory to activation.

As would be expected, platelets from uremic patients may be unusually sensitive to medicines that decrease platelet function. Aspirin has been reported to produce a greater prolongation of the bleeding time in uremic patients than in controls, an effect that may be attributable to more than the irreversible inhibition of COX-1.[283] Similarly, β-lactam antibiotics that prolong the bleeding time may also have a greater effect in uremic patients and may increase the risk of bleeding, particularly those antibiotics cleared by the kidney.[100,265]

Mild thrombocytopenia in chronic renal failure likely reflects a combination of decreased marrow production and shortened platelet survival.[265] However, a platelet count below 100,000/μL should alert the physician to the possibility of a systemic disease, such as multiple myeloma, systemic vasculitis, hemolytic uremic syndrome, preeclampsia, or renal allograft rejection, or an adverse reaction to a drug, such as heparin. Erythropoietin deficiency can also contribute to the hemostatic defect of uremia. Consistent with this concept, defective tyrosine phosphorylation in uremic endothelial cells is restored when erythropoietin is added.[284]

Management of Uremic Bleeding

Prolonged bleeding times and abnormal platelet aggregation studies are common findings in uremic patients, but they do not always predict an increased risk for hemorrhage or constitute an indication for transfusion or therapeutic intervention. If a patient with abnormal platelet function and a long bleeding time requires an invasive procedure, such as a kidney or lung biopsy or a laparotomy, and has no history to suggest an increased risk for bleeding, it may be less risky to perform the procedure without specific treatment to correct the platelet defect than to delay the intervention and attempt to normalize the laboratory values.

When therapy is indicated, the best strategy to improve hemostasis is to perform dialysis. Dialysis improves platelet function, normalizes the prolonged bleeding time, and reduces the risk of bleeding. For example, intensive dialysis decreases the occurrence of acute GI bleeding, a major cause of morbidity and mortality in patients with acute renal failure. Peritoneal dialysis and hemodialysis are equally effective, but evidence of in vivo platelet activation is only seen in patients treated with hemodialysis.

If bleeding does complicate a procedure, the cause is most likely structural and the bleeding should be managed as it would be in patients without renal failure. However, angiodysplasia and erosive esophagitis are more common causes of upper GI bleeding in uremic patients than in those with normal renal function.[255] Patients with chronic renal failure who present with hemorrhage should be evaluated as are other bleeding patients; uremia should not be assumed to be the cause of bleeding.

Apart from intensive dialysis, several treatment modalities have been reported to shorten the bleeding time and improve hemostasis, but well-controlled studies are lacking. Therefore, therapy for bleeding in patients with chronic renal failure should take into consideration the severity of bleeding, the anticipated severity of the hemostatic risk from surgery or trauma, and the risks of the therapy.

Options include DDAVP, which can be given intravenously or subcutaneously at a dose of 0.3 mg/kg. Such treatment has been reported to shorten the bleeding time in 50% to 75% of uremic patients. This correction occurs within 30 to 60 minutes and lasts for up to 4 hours, correlating with increases in the overall plasma concentration of vWF and in the fraction of vWF consisting of higher-molecular-weight multimers. DDAVP has been reported to be effective in preventing surgical bleeding in uremic patients, but controlled trials of its efficacy are lacking. Side effects of DDAVP are uncommon but may include facial flushing, mild tachycardia, water retention, hyponatremia (sometimes severe enough to cause seizures), arterial thrombosis, and memory loss. DDAVP stimulates the release of vWF from endothelial cells, which may account for its therapeutic effect, but other mechanisms may be involved, including a direct priming effect on the platelets.

Increasing the hematocrit, either by red blood cell transfusion or by treatment with recombinant human erythropoietin, can correct the bleeding time and possibly reduce the tendency to bleed. It has also been proposed that in addition to localizing the platelets along the vessel wall, erythrocytes facilitate activation of platelets by releasing ADP, a contribution diminished by anemia.[285]

Conjugated estrogens have also been reported to shorten prolonged bleeding times in uremic patients and to correct the bleeding diathesis.[286] Even a single 50-mg dose of oral conjugated estrogen (Premarin) may be effective. In support of this, conjugated estrogens have been shown to shorten the prolonged bleeding time in uremic rats.[280] The correction of the bleeding time in this model was abolished by the nitric oxide precursor L-arginine, and administration of estrogens to uremic rats decreased the expression of nitric oxide synthase. These findings suggest that the estrogen effect on hemostasis in uremia might be mediated by changes in nitric oxide synthesis.

Some studies have reported that cryoprecipitate infusions shorten the bleeding time in patients with uremia, but others have not; it is unlikely that the benefit justifies the risk.

Liver Disease

The bleeding diathesis observed with fulminant or end-stage liver disease is multifactorial, with contributing causes including thrombocytopenia, anemia, deficiencies in liver-synthesized coagulation factors, and excessive fibrinolysis.[287,288] Patients with chronic liver disease and hepatic cirrhosis of various causes have been reported to have prolonged bleeding times, and these disorders may be associated with other platelet function abnormalities possibly related to a decrease in GPIb.[289] Although some have shown an association between prolonged bleeding time and GI hemorrhage in some studies of cirrhotic patients,[290] others showed that the bleeding time and platelet aggregation abnormalities correlated best with the degree of thrombocytopenia,[291] suggesting that no specific platelet function defect exists in liver disease. An aspirin-like defect has been reported in patients with severe liver disease, with defective aggregation and TXA_2 production.[292] Interestingly, one study showed that platelets obtained from the portal circulation of patients with hepatocellular cancer on a background of cirrhosis showed decreased and delayed aggregation in response to collagen compared with circulating platelets.[293] In addition to portal hypertension and esophageal varices, this finding raises the possibility that localized vascular bed factors (including increased prostacyclin) may contribute to variceal bleeding.

Because patients with cirrhosis often have a complicated hemostatic picture that includes thrombocytopenia, decreased fibrinogen levels, and prolonged prothrombin and aPTTs, one might expect this to uniformly produce a severe bleeding diathesis. However, recent studies have shown that the hemostatic defects in these patients are at least partially compensated through several mechanisms. The potential to bleed because of thrombocytopenia is reduced because vWF levels are often elevated and a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13 (ADAMTS13) activity is decreased,[294,295] perhaps as a consequence of decreased synthesis by hepatic stellate cells. The decreased concentrations of procoagulant factors are balanced by the decreased concentrations of anticoagulant proteins.[296] Dysfibrinogenemia produces a less severe hemostatic defect because of decreased plasminogen levels.[297,298] This balance may easily be tipped in either direction, favoring either bleeding or thrombosis.

Although patients with cirrhosis may have platelet dysfunction, it is usually not associated with serious bleeding. Bleeding in these patients cannot be predicted with routine diagnostic tests, such as the platelet count and PT.[299]

In addition to bleeding, thrombotic episodes are not uncommon in patients with cirrhosis. In advanced cirrhosis, portal or mesenteric thrombosis may occur, possibly because of stasis in the portal system. Underlying thrombotic disorders may increase the thrombosis risk; examples of these include hereditary thrombophilia, MPNs, and nonalcoholic fatty liver disease. Another factor that increases the risk of thrombosis in patients with liver disease is excessive replacement with fresh-frozen plasma or administration of procoagulants. In conclusion, patients with liver disease are at increased risk for both bleeding and thrombosis, and these complications cannot be predicted with routine tests. Controlled studies are required both to better predict these risks and to help guide the management of these complications.

PLATELET DYSFUNCTION RELATED WITH EXTRACORPOREAL CIRCUITS

Although cardiopulmonary bypass (CPB) is accompanied by decreased plasma levels of coagulation factors and increased fibrinolytic activity, abnormal platelet function is also a prominent observation in these patients. A fall in the platelet count and platelet dysfunction are seen in most patients undergoing bypass surgery with either a bubble or a membrane oxygenator.[300] Typical findings after bypass surgery include a prolonged bleeding time (longer than expected for the degree of thrombocytopenia), decreased platelet aggregation, decreased platelet agglutination in response to ristocetin, and depletion of platelet α-granule and dense granule contents.[300] Despite these abnormalities, excessive bleeding is uncommon, occurring only in about 5% of patients. Bleeding, usually manifesting as excessive chest tube drainage (defined as >100 mL/hr), has many causes, including surgical complications, excessive protamine dosing, heparin rebound, and possibly platelet function abnormalities.[301-305]

As with hemodialysis, the platelet defect caused by CPB is most likely a consequence of platelet activation and fragmentation within the extracorporeal circuit. The severity of the platelet abnormalities correlates with the duration of the bypass procedure.[306,307] With uncomplicated surgery, platelet function returns to normal in 1 hour[306]; however, a much longer time may be required in some patients,[308] and the platelet count typically does not return to normal for several days.[305] Thrombocytopenia is caused by hemodilution and deposition of platelets on the bypass circuit and, to a lesser extent, sequestration of damaged platelets in the liver. Platelet dysfunction during bypass may be caused by reversible adhesion and aggregation of platelets on fibrinogen adsorbed from plasma onto the bypass circuit material, mechanical trauma and shear stress, cardiotomy suction, trace concentrations of circulating thrombin and ADP, complement activation, hypothermia, blood conservation devices; bypass priming solutions; and, with bubble oxygenators, exposure of platelets to the blood–air interface.[100] CPB consistently induces the formation of platelet fragments, or membrane *microparticles,* evidence that the platelet surface membrane is subjected to severe mechanical stress and activation during the procedure.[307] Thus considerable platelet activation and aggregation occur during CPB, which leads to deleterious effects from substances released from the platelets and the new adhesive molecules exposed on their surfaces, and renders the platelets relatively refractory to activation by agonists.

Another surgical cause of platelet dysfunction relates to the use of deep hypothermic circulatory arrest in some surgeries. This procedure involves cooling the vital organs to temperatures between 15°C and 22°C (59°F and 71.6°F) for the purpose of neuroprotection during complex surgeries of the aortic arch or intracerebral aneurysms.[309] During the period of deepest hypothermia, the circulation is stopped, making for bloodless surgical fields. Complications of deep hypothermic circulatory arrest include coagulopathy and neurologic sequelae, with evidence that the latter problem may involve hypothermic activation of platelets and formation of microaggregates.[310] Treatment with $\alpha_{IIb}\beta_3$ inhibitors, such as eptifibatide or tirofiban, may improve neurological outcomes by preventing microvascular occlusion.[310]

A study on the use of aspirin in patients undergoing coronary artery bypass grafting indicates that earlier practices of avoiding platelet inhibitors may in fact lead to increased morbidity of all types, ranging from death to ischemic complications involving the heart, gut, and kidneys.[311] Administration of aspirin within 48 hours of surgery reduced the risk of dying by one-third and the risk of nonischemic complications by approximately two-fifths. In the same study, it was noted that the patients who received either platelets or antifibrinolytic therapy to reduce postoperative bleeding were at increased risk for adverse complications and death. Thus, except in the setting of acute hemorrhage with evidence of platelet dysfunction, platelet

transfusion should be avoided. Likewise, it is perhaps best to treat patients with aspirin soon after bypass surgery to decrease the incidence of deleterious effects. In addition to the known benefit of aspirin in reducing the risk of graft occlusion in patients undergoing coronary artery bypass grafting, early institution of aspirin also is warranted for patients who have undergone CPB for other reasons and in whom aspirin therapy is not otherwise contraindicated.

When postoperative blood loss is greater than anticipated, it can be treated with DDAVP after cessation of bypass, but most clinical trials have not demonstrated a beneficial effect of this agent.[312,313] Benefits of DDAVP were more apparent in patients undergoing more complex cardiac surgical procedures. Potential risks of DDAVP include hyponatremia, hypotension, and thrombosis.[312]

Attempts have been made to prevent platelet activation during bypass surgery in humans and experimental animals by infusion of prostaglandin E_1 or prostacyclin. By increasing the platelet concentration of cAMP and reducing platelet responsiveness, these agents reduce the risk of thrombocytopenia and platelet dysfunction.[314] However, the hypotensive properties of these agents limit their usefulness. Antifibrinolytics (tranexamic acid, ε-aminocaproic acid, aprotinin) have been shown to reduce blood loss after CPB.[315] Aprotinin has been studied for its potential to protect platelets from activation by thrombin, plasmin, and other proteases generated during CPB. At high doses, aprotinin appears better than either ε-aminocaproic acid or desmopressin at reducing postoperative blood loss and is at least as good as tranexamic acid.[316] However, aprotinin has been reported to increase mortality and renal toxicity after CPB. These findings resulted in its withdrawal from the market. However, the European Medicines Agency recently lifted this suspension in Europe.

MISCELLANEOUS

Hypothermia

Hypothermia is defined as core body temperature below 35°C or 95°F and is classified as mild (32-35°C or 90-95°F), moderate (28-32°C or 82-90°F), severe (20-28°C or 68-82°F), and profound (below 20°C or 68°F). Major causes of hypothermia are exposure to cold weather or immersion in cold water, but hypothermia can also be caused by dehydration, severe trauma, massive transfusion, head injury, burns, sepsis, and drugs (e.g., alcohol, sedatives, hypnotics). Age is an important risk factor because elderly adults and newborns are particularly prone to hypothermia. Hypothermia is also intentionally induced in some cardiac operations (see the section on extracorporeal circulation).

Mild hypothermia is usually well tolerated, but mortality increases when the core body temperature falls below 20°C. In animals, hypothermia causes thrombocytopenia because of platelet sequestration in the spleen and liver. Hypothermia inhibits platelet aggregation in response to thrombin and thromboxane, increases platelet expression of P-selectin, and decreases expression of the GPIb-IX-V complex.[317] Both the thrombocytopenia and the functional defects are reversible, returning to normal when the body temperature normalizes.

DISSEMINATED INTRAVASCULAR COAGULATION

Disseminated intravascular coagulation is sometimes associated with acquired storage pool disease, believed to be the result of chronic platelet stimulation and resulting in the formation of so-called *exhausted platelets.*[318] The elevated levels of fibrin(ogen) degradation products and reduced fibrinogen concentrations, which are hallmarks of this disorder, may lead to reduced platelet function. Although fibrin(ogen) degradation products can impair platelet aggregation in vitro, the concentrations required to do so are unlikely to be generated in vivo.[319] Platelet dysfunction only occurs with severe hypofibrinogenemia because only small amounts of fibrinogen are needed to saturate the fibrinogen receptors on platelets.[320]

ANTIPLATELET ANTIBODIES

Immunoglobulins may bind to platelets in a specific or nonspecific fashion and can disrupt platelet function. In conditions such as immune thrombocytopenic purpura (ITP), systemic lupus erythematosus (SLE), and platelet alloimmunization, the antibodies can trigger accelerated platelet destruction and subsequent thrombocytopenia. Surviving platelets, known as *stress platelets,* display enhanced function.[321] Indeed, bleeding times in ITP may be shorter than expected for the degree of thrombocytopenia. Sometimes, however, the hemorrhagic tendency is out of proportion to the degree of thrombocytopenia or persists after the platelet count returns to normal, suggesting that the bound antibody may perturb platelet function. Immune thrombocytopenia is common; significantly impaired hemostasis caused primarily by antibody-mediated platelet dysfunction is not. In one study, 3 of 49 patients with ITP whose platelet counts had recovered after therapy with either corticosteroids or splenectomy continued to display elevated bleeding times and persistence of mucocutaneous hemorrhage.[322]

In some patients with ITP or SLE, platelet dysfunction may be suspected because mucocutaneous bleeding symptoms occur despite platelet counts that are usually sufficient for normal hemostasis (>50,000/μL), and the bleeding time may be longer than expected for the degree of thrombocytopenia. Patients with antiplatelet antibodies may exhibit defective platelet function in vitro even if they do not have prolonged bleeding times or clinical symptoms of excessive bleeding, a situation similar to that which occurs with aspirin ingestion or with renal disease. For example, in two studies, 13 of 19 patients with ITP demonstrated impaired platelet aggregation to ADP, epinephrine, or collagen.[323,324] In two other studies, 22 of 35 patients with SLE were found to have decreased platelet aggregation in response to these agonists.[325,326] The platelet function abnormalities appear to be antibody mediated because IgG purified from the plasma or eluted from the platelets of these patients inhibit the aggregation of normal platelets.

Platelet antibodies may affect several aspects of platelet function. The most frequently observed abnormality is absence of platelet aggregation in response to low concentrations of collagen and absence of the second wave of irreversible aggregation in response to ADP or epinephrine. This pattern is identical to the abnormalities caused by aspirin, described earlier. In ITP and SLE, the abnormal aggregation may be related to a reduction in the contents of dense- and α-granules or to an activation defect manifested by diminished synthesis of TXA_2.

Autoantibodies or alloantibodies usually impair the function of the antigen against which they are targeted. For example, alloantibodies (e.g., anti-Pl^{A1}) and autoantibodies that bind to $\alpha_{IIb}\beta_3$ produce a syndrome similar to Glanzmann thrombasthenia.[327-331] These antibody-associated thrombopathies can be severe. It is not surprising that many of the antiplatelet antibodies target $\alpha_{IIb}\beta_3$ because this is the most abundant receptor on the platelet surface and required for all aggregation responses.[332] Antibodies that target GPIb have also been described, in one case producing a syndrome of severe refractory thrombocytopenia and a functional defect resembling that observed in Bernard-Soulier syndrome.[333] An interesting aspect of antibodies against GPIb is their association with more severe thrombocytopenia than that observed with antibodies directed against other antigens.[334] This finding is consistent with the observations that anti-GPIb antibodies inhibit megakaryopoiesis[335] and proplatelet formation in vitro.[336] Autoantibodies that target GPIa (integrin α_2),[337,338] GPIV,[338] and GPVI[339,340] have also been described.[339,341]

Platelet-activating antibodies have been described. Of particular interest is the report of a patient who presented with immune thrombocytopenia and an antibody against CD9 (a member of the tetraspanin protein family) that was capable of activating normal platelets.[342] After recovery of the platelet count, the patient relapsed, this time with an antibody described against the platelet Fc receptor, FcγRIIA. The latter antibody blocked the capacity of the first antibody to activate platelets, confirming that activation involved stimulation of the Fc receptor.

Platelets that have been activated and induced to secrete but have not been incorporated into aggregates are likely to be refractory to platelet agonists and deficient in secretory granule contents, essentially leading to an acquired storage pool deficiency, which has also been described in association with autoantibodies.[343]

CHAPTER 133

DISEASES OF PLATELET NUMBER: IMMUNE THROMBOCYTOPENIA, NEONATAL ALLOIMMUNE THROMBOCYTOPENIA, AND POSTTRANSFUSION PURPURA

Donald M. Arnold, Christopher Patriquin, Lisa J. Toltl, Ishac Nazi, James Smith, and John Kelton

Platelets are anucleate cells that are required for primary hemostasis. Platelets have a life span of 7 to 10 days in circulation, after which time they are cleared by the cells of the reticuloendothelial system (RES), including the spleen. Platelet production is stimulated by thrombopoietin (TPO), a hormone that is constitutively secreted by the liver, which binds to its receptor c-Mpl on platelets, hematopoietic progenitor cells, and bone marrow (BM) megakaryocytes. When TPO is bound to c-Mpl, it is internalized, degraded, and removed from the circulation; thus, when the platelet count is low, free TPO levels are high, and more platelets are produced; when platelet counts are high, circulating TPO levels are low, and platelet production declines. This primitive feedback system is very effective at maintaining the platelet count at a stable level.

Immune-mediated platelet disorders disrupt normal regulation of platelet number because of cell-mediated or antibody-mediated platelet destruction or megakaryocyte injury. Antibodies that target self (autoimmune) or nonself (alloimmune) antigens on platelets can cause severe thrombocytopenia. Immune thrombocytopenia (ITP) is characterized by autoantibodies directed against platelet glycoproteins. Neonatal alloimmune thrombocytopenia (NAIT) is an example of a thrombocytopenic syndrome caused by platelet alloantibodies. Posttransfusion purpura (PTP) has features of both allo- and autoantibodies. These platelet disorders have related features yet are distinct clinical syndromes (Table 133-1). The pathophysiology, clinical manifestations, and management of each of these disorders are discussed in this chapter.

IMMUNE THROMBOCYTOPENIA

Immune thrombocytopenia is a common autoimmune disease characterized by low platelet count levels that can be associated with an increased risk of bleeding. Increased platelet destruction resulting from platelet autoantibodies is the hallmark of ITP. Recently, however, it has become evident that relative platelet underproduction is also an important feature of this disorder. Conventional treatments, including corticosteroids, intravenous immunoglobulin (IVIG), immunosuppressant drugs, and splenectomy, are aimed at preventing platelet destruction. TPO receptor agonists, a new class of medications that work by increasing platelet production, represent the most significant advance in ITP management since the first description of the efficacy of IVIG in the early 1980s. In addition to changing the paradigm as to the pathogenesis of ITP, this milestone set the stage for clinical trials of TPO receptor antagonists and was the catalyst for key papers including the report of an international working group on the standardization of terminology in 2009[1] and the development of the American Society of Hematology (ASH) Guidelines on diagnosis and management of ITP in 2011.[2]

Epidemiology

The natural history of ITP is different in children and adults. For the majority of children, ITP presents acutely and resolves within several weeks even in the absence of intervention. Seasonal variability suggests that a viral infection may trigger the disease in many children. Conversely, adult-onset ITP tends to be insidious in onset and is characterized by a chronic or remitting and relapsing course.

Incidence and Prevalence of Childhood Immune Thrombocytopenia

The incidence of acute ITP in children is estimated at 1.9 to 6.4 per 100,000 per year. Nearly 70% of childhood ITP occurs between the ages of 1 and 10 years with the peak prevalence between 4 and 6 years. Most studies in children report an overall male predominance in early childhood and equalization or reversal to female predominance in older children. Reported prevalence estimates are 12.6 per 100,000 for girls and 9.3 per 100,000 for boys in the older age groups.

Adult Immune Thrombocytopenia

Incidence estimates for adult-onset ITP are reported to be between 1.6 to 3.9 per 100,000 per year.[3] A retrospective analysis from the United Kingdom described a bimodal distribution for men, with peak incidences before the age of 18 years and between 75 and 84 years of age. Relatively stable incidence rates were found in women up to the age of 60 years with a steady increase thereafter. The incidence of ITP has been reported to double in patients after age 60 years.

The overall prevalence of ITP in adults has been estimated at 9.5 per 100,000, ranging from 4.1 per 100,000 in younger ages (19-24 years) to 16 per 100,000 in older age groups (55-64 years). Other investigations have reported male and female prevalence rates of 16.6 and 27.2 per 100,000 adults, respectively, for those ages 18 to 64 years, with rates increasing significantly after the age of 65 years. The prevalence in women is reported to be nearly double that in men; however, this trend is attenuated in older age groups and may revert to a male predominance after the age of 65 years. Indeed, the prevalence of ITP in older men is reported to be as high as 38.3 per 100,000. Adult incidence and prevalence rates may reflect a true increase in risk of disease with age or measurement bias because of a higher likelihood of discovering incidental thrombocytopenia with more frequent medical visits.

Table 133-1 Antibody-Mediated Thrombocytopenic Disorders Caused by Autoantibodies (Immune Thrombocytopenia), Alloantibodies (Neonatal Alloimmune Thrombocytopenia) or Potentially Both (Posttransfusion Purpura)

	Immune Thrombocytopenia	Neonatal Alloimmune Thrombocytopenia	Posttransfusion Purpura
Immune reaction	Autoimmune	Alloimmune	Features of both allo- and autoimmunity
Incidence	Five per 100,000 population	40 per 100,000 births (or one per 2,500)	One per 100,000 blood transfusions
Principal antigenic target	GPIIb/IIIa	HPA-1a	HPA-1a plus autoantigens
Nature of the antibody	Intermittent	Persistent (past 1 year)	Persistent often at high titers
Mode of sensitization	Autoantibody	Alloantibody	Features of allo- and autoantibodies
Sensitizing event	Mostly unknown; some viral illnesses, chronic infection	Exposure to fetal platelet antigens early in first pregnancy	Blood transfusion (RBCs or platelets) 5-10 days earlier
Bleeding frequency	Uncommon	Common	Very common
Epidemiology	Higher incidence in children and elderly adults; female predominance in early adulthood	Majority affects fetus or newborn carrying the HPA-1a antigen	Almost all are HPA-1bb women sensitized by previous transfusion or pregnancy

GP, Glycoprotein; *HPA,* human platelet antigen; *RBC,* red blood cell.

Pregnancy

Thrombocytopenia commonly occurs during pregnancy. Incidental thrombocytopenia of pregnancy is the most common cause followed by pregnancy-related vascular disorders and pregnancy-associated ITP.[4]

Incidental thrombocytopenia of pregnancy (also called gestational thrombocytopenia) may represent a physiological state. It is characterized by mild thrombocytopenia with platelet counts generally greater than 70×10^9/L, occurs late in pregnancy, and is clinically insignificant for the mother or baby. Treatment is not required.

Pregnancy-related vascular disorders are the next most common cause of thrombocytopenia during pregnancy. These disorders include preeclampsia, microangiopathy (including the HELP syndrome, which is characterized by hemolysis, elevated liver enzymes, and a low platelet count), and acute fatty liver. Platelet counts tend to be mildly reduced, and hypertension and other features are invariably present.

Immune thrombocytopenia is an uncommon cause of thrombocytopenia in pregnancy, and when mild, it can be difficult to distinguish from incidental thrombocytopenia of pregnancy. Differences are that pregnancy-associated ITP may present early, thrombocytopenia can be severe, and platelet counts typically increase after ITP-specific therapies such as IVIG or corticosteroids. During pregnancy, platelet count thresholds for instituting ITP treatment are the same as those for women who are not pregnant; in the absence of bleeding, treatment is rarely indicated unless the platelet count is below 20×10^9/L. Although vaginal deliveries are thought to be safe for mothers with ITP, even if the platelet count is very low, most clinicians attempt to maintain the count above 20 to 30×10^9/L. Epidural anesthesia is not recommended unless the platelet count is above 70 to 80×10^9/L, although this practice is operator driven and based on little evidence. IVIG and corticosteroids are generally safe in pregnancy, but corticosteroids can be associated with hypertension and other morbidities. Splenectomy is rarely indicated during pregnancy because most women can successfully be managed with less aggressive therapy. Immunosuppressant medications, such as azathioprine, have been used in pregnancy but should be reserved for refractory pregnancy-associated ITP with bleeding. The risk of severe thrombocytopenia in the newborn caused by passive transfer of maternal antiplatelet autoantibodies is estimated at approximately 10%.

Pathophysiology

Immune thrombocytopenia is caused by increased platelet destruction and impaired platelet production. Until recently, the pathogenesis of immune-mediated thrombocytopenia was mainly attributed to platelet-reactive autoantibodies. However, it is now evident that the pathophysiology of ITP is more complex and involves alterations in cellular immunity and immune-mediated megakaryocyte injury.

The antibody hypothesis began with evidence implicating a plasma factor in the blood of patients with ITP. In one of the first experiments, William Harrington infused blood from ITP patients into normal volunteers and observed a decrease in the platelet counts in most recipients.[5] This circulating "factor" was later identified as an immunoglobulin (IgG) that bound to the surface of platelets. In further studies, investigators were able to quantify platelet-associated IgG (PAIgG) on or inside platelets; however, this test failed to discriminate between immune and nonimmune thrombocytopenia. Assays that detect antibodies directed against specific platelet glycoproteins (GPs), specifically GPIIb/IIIa or GPIb/IX, exhibit improved specificity but have sensitivities that range from 55.4% to 66%. Autoantibodies against platelet GPs target those cells for rapid destruction in the RES, particularly the spleen. Peptides released from phagocytosed platelets may be processed and presented to specific T cells, which in turn stimulate B cells to produce additional platelet autoantibodies. This process, known as epitope spreading, may explain why patients may have autoantibodies targeting a variety of different platelet antigens in their serum.

In ITP, platelet production does not compensate for the increased platelet destruction, suggesting that BM megakaryocytes may also be impaired. Evidence supporting reduced platelet production comes from at least two sources. First, studies using radiolabeled autologous platelets demonstrate normal or reduced platelet turnover in ITP.[6] Second, the capacity of TPO receptor agonists to raise the platelet counts in patients with ITP[7] indicates reduced production. Megakaryocytes also express GP receptors, which may render them targets of ITP autoantibodies. Indeed, in vitro studies have shown suppression of megakaryocyte growth and maturation by the IgG fraction of ITP plasma, which may explain why platelet production is decreased. The mechanisms invoked to explain the development of thrombocytopenia in the face of platelet autoantibodies include opsonization and clearance, direct activation of complement, or cellular destruction via apoptosis.

In addition to the effect of autoantibodies, cytotoxic T cells from ITP patients may exert direct cytolytic effects on platelets. Patients with active ITP but without detectable platelet autoantibodies have $CD8^+$ T cells that induce platelet lysis in vitro. In contrast, $CD8^+$ T cells from patients in remission do not show significant platelet reactivity. Furthermore, $CD3^+$ cells from ITP patients exhibit increased expression of genes involved in cell-mediated cytotoxicity such as tumor necrosis factor-α (TNF-α), perforin, and granzyme A and B relative to control participants, and $CD8^+$ T cells exhibit increased expression of FasL (Fas–Fas ligand) and TNF-α.

In the broadest sense, autoimmunity develops because of a breakdown in regulatory checkpoints that occurs during development or maturation of the immune system.[8] Although the events that trigger a loss of self-tolerance to platelet GPs and the development of ITP are largely unknown, ITP patients exhibit immune alterations, which may explain why they develop autoreactivity to platelet antigens. These include dysfunctional cellular immunity because of Th0/Th1 polarization, decreased regulatory T cells, and autoreactive platelet-specific cytotoxic T cells. In addition, ITP patients can have increased circulating levels of cytokines and soluble factors that promote the survival of self-reactive T and B cells, including BAFF (B-cell activating factor), APRIL (a proliferation-inducing ligand), and BIM (Bcl-2 interacting mediator of cell death). Alterations in proteins involved in proapoptotic pathways designed to delete self-reactive T cells, such as Fas, interferon (IFN)-γ, interleukin (IL)-2 receptor β (IL2RB), Bax, and caspases 8 and A20, have also been demonstrated.

Infection is another stimulus for the formation of platelet reactive autoantibodies. Cross-reactive antibodies (molecular mimicry) have been best described with infections with *Helicobacter pylori,* HIV or hepatitis C virus (HCV). *H. pylori*-associated ITP is discussed later.

Clinical and Laboratory Features

Thrombocytopenia

Thrombocytopenia is the defining feature of ITP. The international working group on standardization of terminology in ITP established a platelet below 100×10^9/L as the cutoff for the diagnosis (Table 133-2).[1] The rationale behind this decision was that patients with mild thrombocytopenia (150-100×10^9/L) have a low risk (≈7%) of developing a persistent platelet count of less than 100×10^9/L; platelet counts slightly below 150×10^9/L may be normal for certain ethnic groups, and mild thrombocytopenia may be caused by physiological processes, such as occurs during pregnancy. Nonetheless, primary ITP remains a diagnosis of exclusion, and as such, investigations are aimed at ruling out nonimmune causes, including pseudothrombocytopenia, myelodysplastic syndrome, thrombotic microangiopathies, splenomegaly, or hereditary thrombocytopenia and secondary immune causes such as infection, concomitant autoimmune disease, or lymphoproliferative disorders.

Immune thrombocytopenia may be primary or secondary. Primary ITP, which was previously known as "idiopathic" but is now referred to as "immune thrombocytopenia" (see Table 133-2), occurs for unknown reasons. Secondary ITP is important to recognize because treatment of the underlying cause is often necessary to increase the platelet count. Examples are ITP occurring in the setting of drugs, lymphoproliferative disease, or HIV or *H. pylori* infection.

Molecular mimicry between the highly antigenic *H. pylori* CagA protein and platelet antigens is the suspected mechanism of *H. pylori*–associated ITP.[9] In most patients, *H. pylori* can be successfully eradicated with a 1- to 2-week course of clarithromycin (500 mg twice daily), amoxicillin (1000 mg twice daily), and pantoprazole or omeprazole (20 mg twice daily); however, the effect of *H. pylori* eradication on platelet count levels is variable. In a meta-analysis that included 788 patients, *H. pylori* eradication resulted in platelet counts that were 34×10^9/L higher than those in untreated control participants and 52×10^9/L higher than those in treated patients whose *H. pylori* was not eradicated. Another systematic review evaluating 696 patients reported that 42.7% of treated patients achieved platelet counts above 100×10^9/L; however, the effect was highly dependent on geographical location with the beneficial effect mainly observed in patients from Japan.[10] Evidence-based guidelines for the investigation and management of ITP recommend against routine screening for *H. pylori* in patients presenting with ITP because of the low yield of testing and the low likelihood of a platelet count increase with eradication. However, testing may be warranted in endemic countries where a high response rate to *H. pylori* eradiation has been demonstrated.

Table 133-2 Standardized Terminology and Definitions for Immune Thrombocytopenia Proposed by the International Working Group (Vicenza Consensus Conference) in 2009

Terminology	Definition
ITP	Immune thrombocytopenia (rather than idiopathic or immune thrombocytopenic purpura)
Platelet threshold for ITP diagnosis	$<100 \times 10^9$/L
Primary ITP	ITP with no associated cause (diagnosis of exclusion)
Secondary ITP	ITP in the setting of an underlying cause such as drugs, HIV, or SLE
Newly diagnosed ITP	Designation for patients at diagnosis (rather than "acute" ITP).
Persistent ITP	Sustained or recurrent thrombocytopenia lasting 3-12 months
Chronic ITP	Thrombocytopenia lasting >12 months
Complete response	Achievement of a platelet count of $\geq 100 \times 10^9$/L in the absence of bleeding
Response	Achievement of a platelet count of $\geq 30 \times 10^9$/L and at least a twofold increase from baseline in the absence of bleeding
Refractory ITP	Failure to achieve a response or relapse after splenectomy* and requirement for treatment(s) to minimize the risk of clinically significant bleeding.

ITP, Immune thrombocytopenia; *SLE,* systemic lupus erythematosus.
*Splenectomy failure may not be applicable in children.

Clinical Outcomes: Mortality, Bleeding, and Quality of Life

Most commonly, patients with ITP present with asymptomatic thrombocytopenia. Although some patients bleed with platelet counts less than 30×10^9/L, many do not. Bleeding symptoms characteristic of ITP ("platelet-type bleeding") include skin bleeding (i.e., bruises, nonpalpable purpura, or petechiae), oral hemorrhagic blood blisters (purpura) or oral petechiae; epistaxis, menorrhagia, or gastrointestinal bleeding. The most feared complication is intracerebral hemorrhage.

In children, large prospective registries indicate a rate of intracerebral hemorrhage that ranges from 0% to 0.2% in the first 6 months after ITP diagnosis.[11] In adults, the risk of life-threatening bleeding is higher but remains low. In a retrospective cohort study spanning 7 years, two of 117 (1.7%) adults with chronic ITP developed intracerebral hemorrhage. In a pooled analysis of ITP patients with platelet counts persistently below 30×10^9/L, the estimated rate of fatal bleeding was 0.02 to 0.04 cases per patient-year, and age older than 60 years was a risk factor.[12]

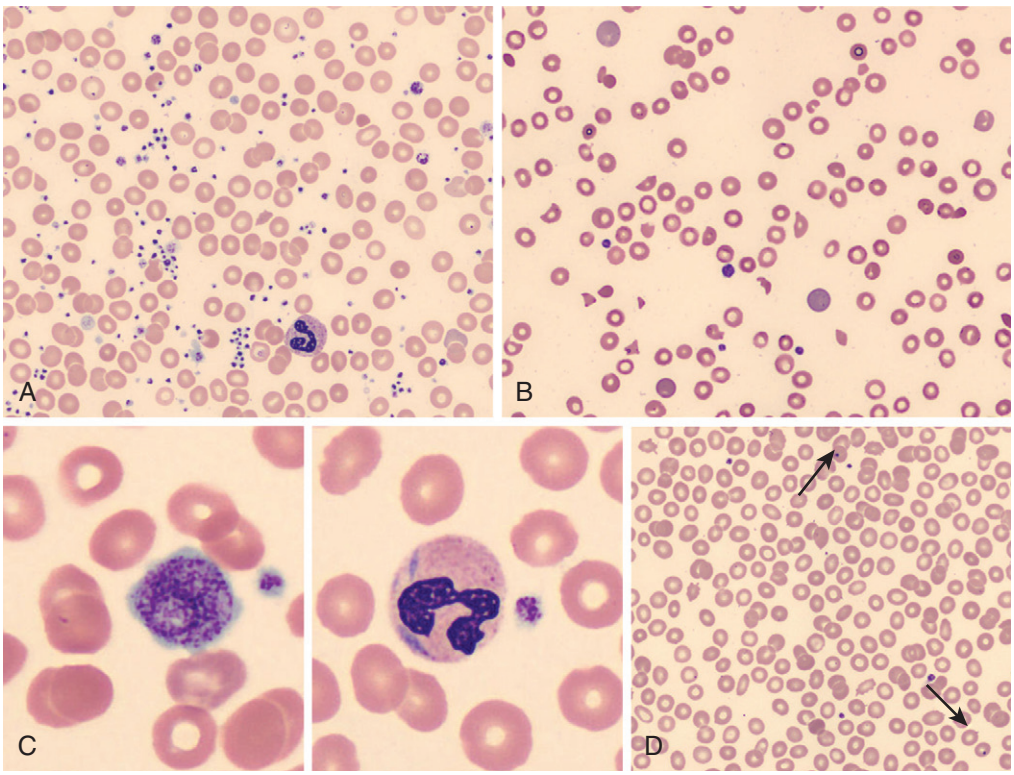

Figure 133-1 BLOOD FILM EXAMINATIONS FROM PATIENTS WITH THROMBOCYTOPENIA. **A,** Pseudothrombocytopenia showing marked platelet clumping. **B,** Schistocytes (fragmented red blood cells) and reticulocytosis in a patient with thrombotic thrombocytopenic purpura. **C,** Macrothrombocyte *(left panel)* and neutrophil-containing cytoplasmic inclusions (Döhle bodies, *right panel*) in a patient with May-Hegglin anomaly. **D,** A patient with immune thrombocytopenia with low platelets and postsplenectomy Howell-Jolly bodies *(arrows)*.

Chronic ITP has been associated with a risk of death that is up to four times higher than that in the general population. ITP patients are more likely to die of bleeding, infection, and hematologic malignancies.[13] Some deaths are attributable to adverse effects of treatment rather than the disease. Quality of life in patients with ITP is lower than that of the general population, which is at least partially because of high prevalence of fatigue that appears to be independent of platelet count levels.

Investigations of Patients With Suspected Immune Thrombocytopenia

Patients presenting with newly identified thrombocytopenia require a careful history and physical examination to uncover potential underlying causes of thrombocytopenia and to assess the risk of bleeding. A complete blood count and review of the blood film is required for all patients with thrombocytopenia (Fig. 133-1). In adults (and in children at risk), HIV and HCV testing should be routinely performed; however, there are insufficient data to support screening for antinuclear antibodies or antiphospholipid antibodies unless other signs and symptoms of systemic lupus erythematosus or antiphospholipid antibody syndrome are present. BM aspiration and biopsy should be reserved for patients with abnormalities affecting other cell lines such as anemia, leukopenia, or macrocytosis. For patients with typical ITP, a BM examination is unnecessary to confirm the diagnosis. Quantitative immunoglobulin levels may be helpful in children to exclude common variable immune deficiency.

Treatment

Although data from clinical studies support the use of corticosteroids for newly diagnosed patients, treatment recommendations beyond first line are based mainly on expert opinion and consensus. Recently, the American Society of Hematology published guidelines for the management of ITP using GRADE methodology to assess levels of evidence associated with each recommendation.[2] Aligned with these guidelines, the authors have proposed a staircase model to illustrate a rational approach to ITP treatment, wherein therapies build on each other, often cumulatively in a stepwise fashion starting from the least toxic (Fig. 133-2). Important areas of uncertainty are optimal treatment of patients who fail first-line therapy and development of decision aids to help patients decide among splenectomy, rituximab, or TPO receptor agonists (see box on First-Line Therapy).

First-Line Therapy

An 8-year-old girl is brought to the emergency department because her mother noticed bruising on her legs. She has had a sore throat and fever for the past 7 days but is otherwise well and not taking any medications. On physical examination, there are a few small bruises on her legs but no petechiae on her skin or purpura in her mouth. Neurologic examination findings are normal, and the spleen is not palpable. The platelet count is 23×10^9/L. The presumed diagnosis is ITP without significant bleeding; thus the decision is made to observe the child in the hospital with no specific treatment. The next day, the platelet count is 33×10^9/L. On day 2, it is 37×10^9/L, and the child is discharged home. One week later, the platelet count is 66×10^9/L, and 1 month later, it is up to 155×10^9/L.

Observation

The vast majority of children with ITP who have either no bleeding or mild bleeding (skin bleeding only) can safely be managed with

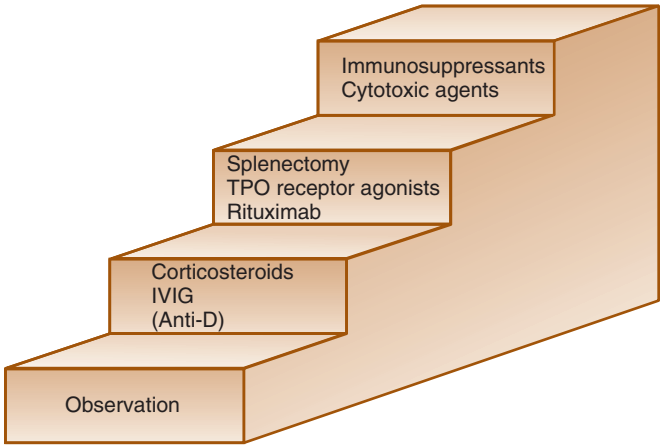

Figure 133-2 STAIRCASE MODEL OF IMMUNE THROMBOCYTOPENIA (ITP) TREATMENT. Therapies build on each other, often cumulatively, in a stepwise fashion starting from the least toxic. After a period of observation, corticosteroid-based treatment is the accepted first-line therapy. Splenectomy, rituximab, and thrombopoietin (TPO) receptor agonists may be reasonable second-line therapy. Rituximab is not currently licensed for ITP. TPO receptor agonists are indicated for patients with ITP who have failed previous therapies, including splenectomy. *(Modified with permission from Arnold DM, Kelton JG: Current options for the treatment of idiopathic thrombocytopenic purpura.* Semin Hematol *44:S12, 2007.)*

observation alone. This recommendation is based on prospective studies demonstrating a low risk of serious bleeding after initial presentation in children and recognition that up to 80% of cases of childhood ITP resolve within 6 months without treatment. A randomized trial that compared prednisone with observation alone in children with ITP who had platelet counts between 10 and 29 $\times$ 10^9/L and had no evidence of bleeding demonstrated no significant difference in the number of days with severe thrombocytopenia (2 and 4 days, respectively). However, if patients present with bleeding, such as epistaxis or mucosal hemorrhage, treatment is required. For adults, a period of observation is also reasonable if there is no evidence of bleeding and the platelet count is above 20×10^9/L. However, most adults eventually require treatment because spontaneous remissions are rare in this population. To reflect current practice, the ASH 2011 guidelines recommend using a platelet count below 30×10^9/L as the threshold for starting treatment.

Corticosteroids

The conventional initial dose of prednisone is 1 to 2 mg per kg for 2 to 4 weeks followed by tapering over a several week period when the platelet count responds. In general, 60% to 70% of adults with acute ITP achieve an initial response; even higher response rates are reported in children. Rates of sustained response (platelet count >100 $\times$ 10^9/L at 6 months) with corticosteroids are generally low and vary from 20% to 47%. With longer follow-up, the risk of relapse is high in adults who sustained an initial complete remission with corticosteroids. Low-dose prednisone (0.5 mg/kg per day followed by a taper) may be as effective as the conventional dose for initial treatment of ITP, but long-term remission rates with either dose remain unsatisfactory. The optimal duration of prednisone treatment and the optimal tapering schedule have not yet been adequately determined.

High-dose dexamethasone, typically administered at a dose of 40 mg/day for 4 consecutive days, has also been evaluated in ITP patients. Uncontrolled cohort studies suggest that this treatment may be effective. In one study that included 125 adults with ITP, almost 40% had a sustained response that lasted 2 to 5 years.[14] Repeated cycles of high-dose dexamethasone (once per month for 6 months) may result in even higher rates of durable remissions, although this effect may simply reflect the total corticosteroid exposure. High-dose dexamethasone can be difficult to tolerate; common side effects include weakness, insomnia, and impaired cognition. Controlled trials comparing prednisone with high-dose dexamethasone are needed.

Intravenous Immunoglobulin and Anti-D

The predominant mechanism of action of high-dose IVIG and anti-D is thought to be via RES blockade. Individuals with low plasma IgG levels exhibit more rapid clearance of sensitized red blood cells (RBCs) (indicating enhanced RES capacity) than those with high levels of plasma IgG, such as those achieved with high-dose IVIG. A competitive model of RES clearance would also explain why anti-D administration to Rh-positive individuals is effective in ITP because IgG-sensitized RBCs compete for Fc receptor occupancy. Other potential explanations for the efficacy of IVIG or anti-D include anti-idiotypic antibodies, stimulation of pro- and anti-inflammatory cytokines, up- or downregulation of various Fc receptors, and the induction of soluble immune complexes. In a mouse model of ITP, transfer of IVIG-primed dendritic cells recapitulated the effect of IVIG.[15]

Based on the results of a meta-analysis of randomized controlled trials in children (n = 410), the probability of achieving a platelet count above 20×10^9/L at 48 hours is lower with corticosteroids than with IVIG (relative risk, 0.74; 95% confidence interval [CI], 0.65-0.85).[16] Similar results have been observed in adults. Common side effects of IVIG include headache, hypertension, and chills. Hemolysis and neutropenia are rare side effects.

Anti-D has been compared with IVIG in children, and the two agents have similar efficacy provided that anti-D is given in high doses (75 μg/kg). Hemolysis invariably occurs after anti-D administration, and rarely, intravascular hemolysis can have a fatal outcome. Consequently, the Food and Drug Administration has issued a black box warning about the safety of anti-D, and the drug has been removed from certain European markets. In general, the use of anti-D is restricted to nonsplenectomized patients who are Rh positive and have a negative direct antiglobulin test result.

Second-Line Therapy

The choice of treatment for patients who relapse after first-line therapy or who fail to respond is controversial. Although splenectomy has been the treatment of choice for many years, rituximab and TPO receptor agonists are currently being evaluated as viable alternatives. Patient preference and access to medications are important considerations.

Splenectomy

Splenectomy was first proposed in 1913 and was subsequently shown to be an effective means of raising the platelet count in most ITP patients. Results of numerous studies indicate that approximately two-thirds of splenectomized patients achieve a response, generally within days.[17] Despite the high success rate with splenectomy, however, patients and physicians are often divided on the desirability of this approach. Identification of predictors of success of splenectomy has only identified younger age as an indicator. Some investigators have found a correlation between response to IVIG and that to splenectomy, and in some studies, evidence of radiolabeled platelet sequestration in a splenic pattern was associated with a good response to splenectomy.

With currently available minimally invasive surgical techniques, complications after splenectomy are uncommon. The overall mortality rate is approximately 1% after laparotomy and about 0.2% after laparoscopic splenectomy. The most frequent perioperative

complications are pneumonia, subphrenic abscess or pleural effusion (4%), major bleeding (1.5%), and thromboembolism (1%). With laparoscopic techniques, patients have less postoperative pain, shorter hospital stays, and fewer wound complications.

Because the spleen is involved in clearance of encapsulated bacteria, asplenic individuals are at risk for infection with *Streptococcus pneumoniae, Neisseria meningitides,* and *Haemophilus influenzae type b* and therefore should receive these vaccinations at least 2 weeks before splenectomy. Poor compliance and vaccine failures contribute to the ongoing risk of serious postsplenectomy infections, which are associated with a 50% to 70% mortality rate.

The lifetime risk of overwhelming postsplenectomy infection is estimated to be 3% with the risk being higher in children younger than 15 years of age and in patients with hematologic malignancies. In a population cohort study of 3812 splenectomized patients in Denmark, the risk of any infection requiring hospitalization was highest in the first 90 days after splenectomy but remained 2.5 times higher than that in the general population thereafter.[18] The risk was lower when the comparison group was nonsplenectomized ITP patients, suggesting that many of the hospitalizations may be attributable to the underlying condition.

Rituximab

Rituximab is an anti-CD20 monoclonal antibody that targets and destroys $CD20^+$ B lymphocytes, some of which are presumably involved in autoantibody production. Rituximab has been widely used in patients with various autoimmune diseases, including ITP, and data correlating cellular profiles with clinical outcomes suggest that its effect may be attributable to improvement in T-cell function and reversion of T-cell abnormalities, downstream effects of B-cell depletion. The effect of rituximab on platelets, autoantibodies requires further study.

In a systematic review of 19 observational studies that enrolled 313 ITP patients of whom 46.2% were not splenectomized, rates of complete response (platelet count $>150 \times 10^9$/L) and overall response (platelet count $>50 \times 10^9$/L) with rituximab were 43.6% (95% CI, 29.5%-57.7%) and 62.5% (95% CI, 52.6%-72.5%), respectively, after a median follow up of 9.5 months.[19] The typical rituximab dose was 375 mg/m^2 administered by intravenous infusion once weekly for 4 consecutive weeks. The median time to response was 5.5 weeks, and responses lasted a median of 10.5 months. Other observational studies have reported lower rates of durable remissions, ranging from 24% at 12 months to 35% at 57 months.

Several completed or ongoing clinical trials have evaluated rituximab as adjuvant therapy for newly diagnosed or relapsed ITP before splenectomy. A pilot randomized trial of 60 nonsplenectomized adults receiving standard of care (which consisted mostly of corticosteroids and/or IVIG) reported no difference between rituximab and placebo for the composite endpoint of platelet count above 50×10^9/L, significant bleeding or requirement for rescue treatment after 6 months. Another randomized trial that included 103 treatment-naive adult patients reported that 31 of 49 (63%) patients in the rituximab plus dexamethasone group and 19 of 52 (36%) patients in the dexamethasone alone group achieved a platelet count of 50×10^9/L or higher after 6 months without rescue treatment (absolute risk reduction 27%; 95% CI, 8%-46%).[20] In a prospective observational study of 60 nonsplenectomized adult patients with ITP who had a median of 2 prior therapies, 24 (40%) achieved a platelet count above 50×10^9/L and at least twice their inclusion value at 1 year, and 20 (33%) maintained their platelet count response at 2 years with rituximab treatment. Low-dose rituximab (100 mg per week for 4 weeks) has been shown to be biologically active in ITP, but the frequency of durable responses is modest.

Rituximab has also been evaluated in a small number of children with chronic ITP. Variable response rates have been reported ranging from 31% to 69%, with sustained responses observed in 43% of patients after a median of 20 months.

Minor infusion-related side effects of rituximab occur in approximately 30% of patients with ITP and include hypotension, rash, sore throat, fever, and rigors. Fatal infusion reactions are rare in patients treated for autoimmune diseases. Serum sickness, characterized by arthropathy, fever, and low serum complement levels, may be more common in children than in adults and often necessitates drug interruption. Progressive multifocal leukoencephalopathy (PML) is a rapidly fatal neurologic syndrome caused by reactivation of latent JC virus in the brain. Rare reports have linked PML with rituximab treatment.[21]

Overall, rituximab has been shown to be effective in some patients. However, rituximab rarely produces a sustained platelet count response. Consequently, the 2011 ASH treatment guidelines gave rituximab a weak (grade 2C) recommendation for patients who have failed corticosteroids, IVIG, or splenectomy.

Thrombopoietin Receptor Agonists

Drugs aimed at increasing platelet production by stimulating the c-Mpl receptor have been investigated for the treatment of thrombocytopenia. Initial studies with recombinant human TPO and pegylated recombinant human megakaryocyte growth and development factor (PEG-rHuMGDF) were halted because of the development of cross-reactive antibodies against endogenous TPO with the pegylated formulation, which led to severe and sustained thrombocytopenia in healthy volunteers. These findings prompted the development of second-generation TPO receptor agonists that have no sequence homology to endogenous TPO. Two such drugs are approved for the treatment of patients with chronic ITP, romiplostim (Nplate, Amgen) and eltrombopag (Promacta/Revolade, GlaxoSmithKline). These agents have demonstrated efficacy even in some patients with refractory disease. Platelet counts generally remain elevated as long as the drugs are continued; when they are stopped, platelet counts tend to rapidly fall back to baseline thrombocytopenic levels.

Romiplostim (administered as a once-weekly subcutaneous injection) is a synthetic peptibody consisting of four peptides linked to an IgG Fc fragment. The molecule binds the c-Mpl receptor at the same location as endogenous TPO and stimulates megakaryocyte proliferation and platelet production through intracellular Janus kinase/signal transducer and activator of transcription (JAK/STAT) and mitogen-activated protein kinase (MAPK) signaling. In a phase III trial, a durable platelet count response (defined as the achievement of a platelet count of 50×10^9/L or higher for 6 or more of the last 8 weeks of treatment) was achieved in 41 of 83 patients (49.4%) receiving romiplostim compared with one of 42 (2.4%) patients receiving placebo.[22] In a subsequent randomized trial that compared romisplostim with standard of care treatment, romiplostim was associated with a higher rate of platelet count responses, fewer treatment failures, fewer splenectomies, less bleeding, and better quality of life.[23] Weekly doses of romiplostim range from 1 to 10 μg/kg; most patients achieve a suitable response with a dose of 3 μg/kg. Weekly doses are titrated up or down, depending on the platelet count response, to maintain the platelet count in the appropriate range (30-100 $\times 10^9$/L).

Eltrombopag (administered as a tablet once daily) is a small molecule, nonpeptide TPO receptor agonist that activates c-Mpl by binding to the transmembrane domain. In contrast to romiplastim, eltrombopag does not compete with circulating TPO for binding to c-Mpl. In a phase III trial, the odds of responding to eltrombopag were approximately eight times higher than with placebo throughout the 6-month treatment period.[24] Durable responses were achieved in 57 of 95 patients (60%) receiving maintenance eltrombopag compared with four of 39 patients (10%) receiving placebo. The time to response was 1 to 2 weeks (similar to romisplostim) with a minimal need for dose titration.

A recent systematic review summarizes the data from randomized trials of TPO receptor agonists. The authors concluded that although romiplostim and eltrombopag were each associated with platelet

count responses, neither significantly improved the rate of severe, life-threatening or fatal bleeding compared with standard of care.[25] This review highlights the need for patient focused outcomes in ITP trials.

TPO receptor agonists are generally well tolerated but have been associated with headache, fatigue, and insomnia. Both drugs have rarely been linked to the development of bone marrow reticulin in patients with ITP; however, this abnormality resolves with discontinuation of the drug, and stem cell disorders have not been reported. TPO receptor agonists have also been associated with thromboembolic events (independent of platelet count), although follow-up analyses have questioned the strength of this association. One study of eltrombopag in patients with advanced liver disease and secondary thrombocytopenia was stopped early because of an increase in the frequency of portal vein thrombosis. Eltrombopag has been associated with serum liver test abnormalities in approximately 10% of patients. Long-term follow-up data for patients treated with these agents are limited (see box on Long-Term Follow-Up).

Treatment of Refractory Immune Thrombocytopenia

As suggested by the International Working Group on standardization of terminology in ITP, the term *refractory ITP* is used to define patients who have failed splenectomy or relapsed thereafter and either exhibit severe thrombocytopenia or have a risk of bleeding that necessitates therapy (see Table 133-2).[1]

Evidence to help guide management of patients with chronic refractory ITP after splenectomy is limited, and treatment has been mainly unsatisfactory. However, TPO receptor agonists provide a new and effective option for this challenging group of patients. The overarching principals of therapy for this population are (1) the goal of treatment is to prevent bleeding with the achievement of a stable, although not necessarily normal, platelet count, and (2) combination therapy may be more effective than treatment with a single agent.

In randomized trials, the response of splenectomized patients to treatment with TPO receptor agonists is less than that of nonsplenectomized patients; however, the difference is small, and response rates in splenectomized patients approach 50%. Although some patients included in the trials had failed up to 5 prior therapies, the results may not be applicable to all patients with refractory ITP seen in clinical practice.

Before the availability of TPO receptor agonists, a systematic review identified rituximab, azathioprine, and cyclophosphamide as agents most often associated with complete responses in patients with refractory ITP.[26] Good response rates have also been reported with the combination of cyclosporine, azathioprine, and CellCept or with the combination of IVIG, intravenous methylprednisolone, vincristine, or IV anti-D followed by maintenance therapy with danazol and azathioprine. Other treatment options include low-dose or alternate-day corticosteroids, repeated doses of IVIG, high-dose chemotherapy, or dapsone. High-dose chemotherapy and stem cell transplantation have also been used successfully in this population, and with the advent of less toxic regimens, this treatment modality may soon become a more acceptable option for selected patients with severe refractory ITP.

Long-Term Follow-Up

The best treatment of patients with ITP who fail first-line therapy remains controversial and depends on the severity of symptoms, side effect profile, and patient preference. Splenectomy has been used for many years and is the treatment option most likely to be associated with durable remissions. Rituximab may achieve a platelet count response in up to 60% of patients, but responses are rarely sustained past 6 to 12 months. TPO receptor agonists (romiplostim or eltrombopag) are associated with a platelet count response in up to 60% of patients as long as treatment is maintained. These drugs are generally well tolerated; however, long-term safety data beyond 5 years are not yet available.

NEONATAL ALLOIMMUNE THROMBOCYTOPENIA

Neonatal alloimmune thrombocytopenia is an uncommon but serious thrombocytopenic disorder that can cause fetal or neonatal bleeding resulting in death or disability. It is important to recognize this disorder because treatment prevents recurrence in subsequent pregnancies. With NAIT, intracranial bleeding can occur during the neonatal period or in utero, in which case the diagnosis is first suspected after an abnormal fetal ultrasonography. The incidence has been estimated to range from one to two in 1000 births; however, it is often underdiagnosed.

Clinical Presentation

Thrombocytopenia may be severe in infants affected by NAIT; often the platelet count is less than 10 to 20 $\times$ 10^9/L shortly after birth. The differential diagnosis is broad and includes septicemia, hypoxia, and birth trauma, among other factors (Table 133-3). Typically, NAIT presents as severe thrombocytopenia, possibly with associated bleeding, in an otherwise healthy neonate with no other explanation for the low platelet count. The thrombocytopenia often worsens hours or days after delivery, likely reflecting increased RES function in the newborn, particularly within the lungs. Without treatment, thrombocytopenia may last for days, but occasionally, it can be severe and can persist for many weeks. Bleeding symptoms range from petechiae and bruising to gastrointestinal or intracranial hemorrhage. Overall, bleeding occurs in up to 20% of neonates with NAIT and has been documented early in pregnancy. For infants with severe thrombocytopenia, mortality estimates of 10% have been reported, and infants with intracranial bleeding may be left with developmental delays and severe, lifelong neurologic deficits.

Table 133-3 Differential Diagnosis of Thrombocytopenia in Newborns

Perinatal hypoxemia
Placental insufficiency
Congenital infection
Sepsis
Toxoplasmosis
Rubella
Cytomegalovirus
Autoimmune
Maternal immune thrombocytopenia
Maternal systemic lupus erythematosus
Disseminated intravascular coagulation
Maternal drug exposure
Congenital heart disease
Hereditary thrombocytopenia
MYH9 macrothrombocytopenia (including May-Hegglin anomaly)
Thrombocytopenia absent radii syndrome
Amegakaryocytic thrombocytopenia
Wiskott-Aldrich syndrome
Fanconi anemia
Hemangioma with thrombocytopenia
Kasabach-Merritt syndrome
Bone marrow infiltration
Congenital leukemia

Pathophysiology

Fetal and neonatal thrombocytopenia in NAIT is caused by the clearance of IgG-sensitized platelets by maternal alloantibodies directed against platelet-specific antigens. The syndrome can be considered analogous to the destruction of fetal RBCs in hemolytic disease of the newborn (HDN) but with a number of differences. Perhaps most importantly, NAIT often presents in a first pregnancy because of maternal sensitization to paternally derived antigens expressed on fetal platelets. In contrast, it is distinctly uncommon for HDN to occur in a first pregnancy without previous sensitization. This difference suggests that unlike RBCs, transplacental passage of fetal platelets or platelet antigens into the maternal circulation occurs early in pregnancy. Another difference is that pregnant women at risk for HDN (e.g., those who are Rh negative) can be identified early by screening, and treatment with anti-Rh immune globulin reduces the risk of sensitization. To date, screening programs for NAIT have not been widely deployed because women at risk are not readily identifiable before sensitization has occurred, and therapies of proven benefit are not currently available. Screening programs for NAIT continue to be an active area of research (see box on Neonatal Alloimmune Thrombocytopenia Versus Hemolytic Disease of the Newborn).

Laboratory Investigation of Suspected Neonatal Alloimmune Thrombocytopenia

The diagnosis of NAIT is established by documenting the presence of a platelet-specific antigen incompatibility between mother and infant (or mother and father) and the presence of maternal antiplatelet alloantibodies directed against the incompatible antigen (Fig. 133-3).[27]

Neonatal Alloimmune Thrombocytopenia Versus Hemolytic Disease of the Newborn

NAIT can be viewed as the platelet equivalent of HDN with some important differences: (1) maternal sensitization by fetal platelet antigens can occur early in the first trimester, (2) NAIT can affect first pregnancies, (3) women at risk for NAIT are not easily identifiable before sensitization and thus are not amenable to universal screening programs, and (4) a specific therapy that targets prevention of platelet antigen sensitization is lacking (e.g., Rh-immune globulin that target RBC antigen exposure).

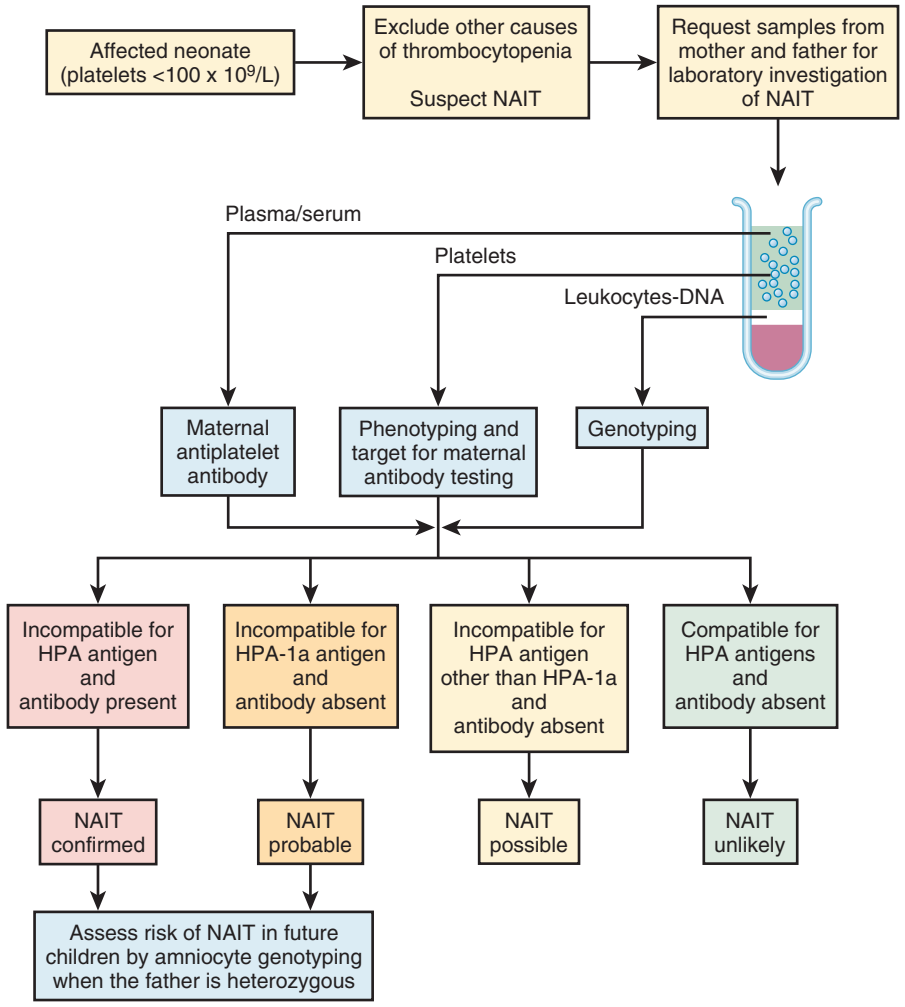

Figure 133-3 DIAGNOSTIC TESTING ALGORITHM FOR INVESTIGATION OF NEONATAL ALLOIMMUNE THROMBOCYTOPENIA (NAIT) AND MANAGEMENT RECOMMENDATIONS BASED ON RESULTS OF TESTING (CURRENTLY USED BY THE ONTARIO PROVINCIAL PLATELET LABORATORY AT MCMASTER UNIVERSITY PLATELET IMMUNOLOGY REFERENCE LABORATORY, 2012). Maternal blood samples are tested for platelet antigens (phenotyping and polymerase chain reaction genotyping) and platelet alloantibodies. Amniocentesis and fetal genotyping are recommended when the father is known to be heterozygous for the incompatible antigen. *HPA,* Human platelet antigen. *(Modified from Arnold DM, Smith JW, Kelton JG: Diagnosis and management of neonatal alloimmune thrombocytopenia.* Transfus Med Rev *22:255, 2008, with permission.)*

Consequently, diagnosis requires allele-specific genotyping to identify maternal–fetal (or maternal–paternal) antigenic mismatch using polymerase chain reaction technology. Serologic confirmation, which requires the documentation of maternal alloantibodies, is more difficult for two reasons. First, *the technology is complex, and relatively few laboratories perform these tests*. In general, most commercial assays detect platelet alloantibodies directed against only a limited number of antigens. This limitation necessitates the use of more specific assays, such as monoclonal antibody immobilization of platelet antigen assays or antigen capture assays.[28] Even these tests are limited by the lack of the monoclonal antibodies required to capture the target protein. An alternative method uses radioimmunoprecipitation, which can detect all of the known alloantibodies described to date. *Second, a proportion of women have no detectable antibodies using currently available laboratory methods*. For example, up to 25% of human platelet antigen-1a (HPA-1a)–negative women with NAIT have no detectable anti–HPA-1a antibody. The explanation for this observation is uncertain.

Alloantibodies recognize epitopes on platelet GPs that are defined by genetic polymorphisms. To date, all of these antigens are the result of single nucleotide polymorphisms or in-frame deletions of the codon. Consequently, platelet typing using genetic analysis is relatively straightforward. The majority of platelet alloantigens occur on GPIIIa, which is the most abundant platelet glycoprotein (50,000-75,000 copies per platelet). GPIIIa, also known as β3, forms a heterodimer with platelet GPIIb to form the integrin $\alpha_2\beta_3$, which serves as the binding site for fibrinogen and enables platelet aggregation.

The most common platelet alloantigen implicated in NAIT is the alloantigen HPA-1a. This important alloantigen is defined by a leucine (HPA-1a) to proline (HPA-1b) substitution at amino acid 33 on GPIIIa. Maternal incompatibility to HPA-1a is implicated in more than 80% of women with NAIT. These women lack the common HPA-1a antigen (i.e., their genotype is HPA-1bb) and during pregnancy, they are immunized with fetal HPA-1a antigen, which is inherited from the father.

The next most commonly implicated antigens in NAIT are HPA-5a5b on glycoprotein Ia/IIa and HPA-15a15b on the glycosylphosphatidylinositol–anchored protein, CD109. Only six of the 17 platelet antigen systems have been defined by maternal alloantibodies to both alleles; these include the HPA 1, 2, 3, 4, 5, and 15 systems. There are a number of other very-low-frequency alleles, the majority of which are expressed on platelet GPIIb/IIIa and are usually found within a single family. Frequently, discrepancies for human leukocyte antigen (HLA) and ABO, which are also expressed on platelets, are found during the course of investigations for NAIT; however, it is unclear whether these are of any clinical consequence.

Management

Management of Infants After Delivery

When NAIT is suspected and depending on the platelet count, treatment should be initiated even before confirmatory test results are available. It is important to appreciate that moderate or severe thrombocytopenia at birth (20-50 $\times$ 10^9/L) can worsen over the next few days. Treatment should be initiated immediately if thrombocytopenia is severe (platelets <20 $\times$ 10^9/L); if there are petechiae or purpura; or if there is evidence of serious bleeding, such as intracranial bleeding on cranial ultrasonography. The initial treatment is high-dose IVIG (1-2 g/kg), which will increase the platelet count in most infants.[29] Platelet transfusions should also be given if the thrombocytopenia is severe and there is evidence of bleeding. Ideally, platelet products for transfusions should be alloantigen compatible. However, if these are unavailable, random donor platelets can be used because they produce adequate increases in the platelet count.[30]

Antenatal Management of the Mother

Women with a previously affected infant with NAIT are at high risk of having another affected infant. Consequently, careful management in subsequent pregnancies is required. Similar to HDN, the disorder is often more severe in subsequent pregnancies than it is in the first. The exception is if the father is heterozygous for the implicated platelet antigen, in which case antigenic testing can be performed by amniocentesis to determine if the fetus is at risk and whether treatment is required.

Antenatal treatment options for at-risk mothers during subsequent pregnancies range from careful observation to IVIG with or without corticosteroids to fetal blood sampling (FBS) and intrauterine platelet transfusion. Invasive strategies that include FBS are associated with a high rate of complications, including fetal death and premature labor; thus a noninvasive approach is often recommended.

The mainstay of antenatal therapy for women with a previously affected infant is high-dose IVIG (1-2 g/kg) administered weekly throughout pregnancy starting at approximately 20 to 24 weeks of gestation. A systematic review summarizing the results of four randomized trials that included 206 women compared weekly IVIG with a variety of other therapies, including alternate dosing of IVIG or IVIG plus corticosteroids.[31] Although no definitive conclusions could be drawn, most clinicians use IVIG for antenatal treatment. Corticosteroids (prednisone or dexamethasone) given in combination with IVIG should be considered for mothers at high risk, such as those with a previously affected infant with intracranial hemorrhage or severe thrombocytopenia or if the response to IVIG is suboptimal.

Fetal Monitoring During Pregnancy

Serial ultrasonography is indicated for fetal surveillance. This provides a simple, noninvasive method for identifying fetal bleeds at an early stage. FBS by percutaneous cannulation of the umbilical or intrahepatic vein may be a way of capturing high-risk fetuses, identifying those who require treatment, and monitoring response to therapy. However, FBS is technically challenging and is associated with significant morbidity and mortality. In one study, 6% of FBS procedures were associated with complications, including fetal death from exsanguination and premature induction of labor.[32] Furthermore, a platelet transfusion protocol based on the detection of fetal thrombocytopenia would necessitate frequent FBS procedures because of the short (7-day) life span of transfused platelets. Because the risks associated with FBS exceed the benefits, routine FBS is not recommended.

Mode of Delivery

There is no evidence that planned cesarean section is safer than uncomplicated vaginal delivery for infants with NAIT. Nonetheless, planned cesarean section delivery can ensure that personnel and resources, including antigen-compatible platelet transfusions, are available without delay.

Population Screening for Neonatal Alloimmune Thrombocytopenia

Universal NAIT screening programs for all pregnant women are not currently available because of the difficulty in identifying at-risk women early and the lack of specific and proven treatments. One study screened 100,448 pregnant women and offered those with HPA-1a antibodies early cesarean section together with compatible platelet transfusions.[33] This approach identified 161 affected infants, of whom three (6%) died or had an intracranial bleed, compared with 10 of 51 infants (20%) born to mothers who were not screened.

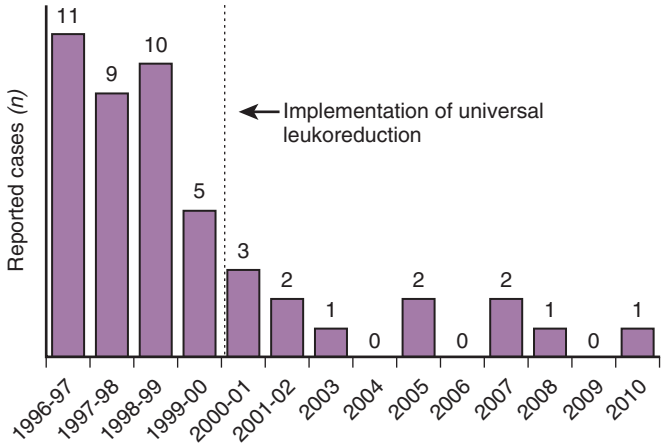

Figure 133-4 CONFIRMED CASES OF POSTTRANSFUSION PURPURA (PTP) REPORTED BY THE UK SERIOUS HAZARDS OF TRANSFUSION (SHOT) SURVEILLANCE PROGRAM. Universal leukoreduction was implemented in late 1999, which coincides with a decrease in new cases of PTP. *(Adapted from Knowles S (ed) and Cohen H on behalf of the Serious Hazards of Transfusion (SHOT) Steering Group.* The 2010 Annual SHOT Report (2011)*, with permission.)*

These results are encouraging, and additional studies of NAIT screening programs are ongoing.

POSTTRANSFUSION PURPURA

Posttransfusion purpura is a rare thrombocytopenic syndrome that is provoked by an alloimmune response against human platelet antigens, most frequently HPA-1a. It occurs in patients—usually women—who have been previously sensitized to platelet-specific antigens and who develop a severe immune reaction after exposure to platelets or platelet antigenic material in blood transfusions.

Epidemiology

Posttransfusion purpura is rare with an estimated incidence of one to two per 100,000 transfusions. Data from the Serious Hazards of Transfusion surveillance program in the United Kingdom indicate a decrease in the incidence of PTP in the past decade (Fig. 133-4).[34] This trend may reflect the move to universal leukoreduction of blood products, which was implemented in 1999. The average number of cases of PTP in the years before (1996-1999) and after (2000-2005) universal leukoreduction was 10.3 and 2.3 cases per year, respectively. Since then, there has also been a shift from RBC concentrates to platelet concentrates as the inciting transfusion event, which may be attributable to the reduction in platelet contamination of RBC products with leukoreduction methods (see box on Clinical Presentation of Posttransfusion Purpura).

Approximately 85% of PTP episodes occur in women, almost all of whom have a history of pregnancy. In a report of 61 patients, the sensitizing event among women was pregnancy alone in 58%, pregnancy or transfusion in 34%, and transfusion alone in 7.5%. Men had associated transfusion histories in 55%; some had no known exposure. PTP has not been reported in children.

Clinical Presentation

Posttransfusion purpura presents as severe thrombocytopenia (platelets $<10 \times 10^9$/L) and bleeding, which may include petechiae, purpura, mucosal hemorrhage, hematuria, or intracranial bleeding. The thrombocytopenia is often refractory to platelet transfusion even with antigen-negative platelets, although this treatment is indicated for patients with bleeding, for whom mortality rates range from 5% to 20%. The thrombocytopenia occurs 7 to 10 days after blood transfusion and typically resolves within weeks. Occasionally, thrombocytopenia may persist for months. Other causes of thrombocytopenia that can mimic PTP include primary ITP, drug-induced ITP, sepsis, disseminated intravascular coagulation, and thrombotic thrombocytopenic purpura. However, the temporal association with blood transfusion and the severity of the bleeding suggest the diagnosis. Patients with PTP may present with features that overlap with heparin-induced thrombocytopenia (HIT), and positive HIT test results in the context of anti-HPA antibodies have been reported. However, thrombocytopenia is less severe with HIT, and severe bleeding is rare.

Clinical Presentation of Posttransfusion Purpura

On postoperative day 8 after spinal surgery, a 43-year-old woman has a platelet count of 3×10^9/L. During the operation, she received 3 units of non–leuko-reduced packed RBCs because of intraoperative bleeding. She is receiving intravenous ampicillin and prophylactic doses of the low-molecular-weight heparin dalteparin. On physical examination, she has extensive oral mucosal purpura and petechiae on both lower extremities. HIT testing results (anti-PF4/heparin enzyme-linked immunosorbent assay and serotonin release assay) are negative. The ampicillin is stopped, and she is treated with IVIG (2 g/kg) and platelet transfusions. Three days later, the platelet count is 4×10^9/L, and the patient develops melena. The presumed diagnosis is posttransfusion purpura; therefore, HPA-1a–negative platelets and high-dose parenteral corticosteroids are administered, and daily plasma exchange is initiated. One week later, the thrombocytopenia and bleeding symptoms resolve. Platelet antibody testing reveals the presence of anti–HPA-1a antibodies.

Diagnosis

The majority of patients with PTP lack the common HPA-1a platelet antigen (i.e., have the HPA-1bb genotype) and have been sensitized by previous pregnancies or transfusions. These sensitizing events result in the development of anti–HPA-1a alloantibodies, the detection of which can be used for serologic diagnosis. Anti–HPA-1a antibodies may persist for many years in these patients.

Pathophysiology

Platelets contain abundant amounts of GPIIb/IIIa. Consequently, even small numbers of platelets or platelet microparticles in RBC concentrates can be immunogenic and lead to the development of PTP. Genotypic analyses indicate that HLA-II alleles DRB3*0101 and DQB1*0201 are associated with PTP, a situation analogous to NAIT. The frequency of immunization depends on platelet alloantigen discrepancy plus the presence of certain immune response genes.

The most intriguing feature of PTP is that the patient's own compatible platelets are destroyed. Furthermore, platelet reactive antibodies can be eluted from both antigen-positive and -negative platelets. Although the mechanism is still poorly understood, potential explanations for this "innocent bystander" phenomenon include immune complex formation, passive antigen adsorption, and autoantibody formation.

Theoretically, immune complexes may form if the anti–HPA-1a antibodies bind soluble antigen. Immune complexes may then bind to platelets through Fc receptors, causing platelet destruction. Alternatively, platelet alloantigens contained within the transfused blood product may be passively adsorbed onto autologous platelets, thereby

converting them from antigen-negative to -positive cells and rendering them targets for immune destruction. Anti–HPA-1a antibodies have been shown to induce platelet activation through release of platelet-derived RANTES (regulated on activation, normal, T-cell expressed and secreted), a proinflammatory and immunomodulatory chemokine involved in multiple immunologic processes, including immunoglobulin synthesis and regulation of T-helper 1/T-helper 2 (Th1/Th2) cytokine homeostasis. In some patients with PTP, alloantibodies have been shown to interfere with the platelet–fibrinogen interaction, thereby increasing the risk of bleeding.

The induction of specific anti-HPA alloantibodies could in turn initiate the formation of platelet-reactive *autoantibodies*. Pan-reactive antibodies can be found when the platelet count is at its lowest level, and serologic analyses in PTP cases demonstrate the presence of reactive IgG and IgM antibodies against GPIIb/IIIa, GPIX, and GPIa/IIa. However, only HPA-specific IgG antibodies persist.[35]

Management

Treatment of PTP should be initiated even before serologic test results for anti–HPA-1a are available. The primary goal of treatment is to abbreviate the period of severe thrombocytopenia and minimize the risk of bleeding. Multiple treatments are often administered simultaneously or in rapid succession.

Patients with PTP require supportive treatment and rapid management of bleeding if it occurs. Nonessential transfusions should be avoided. The mainstay of therapy is high-dose IVIG, which usually results in an increase in the platelet count after 3 or 4 days.[36] High-dose corticosteroids have also been used to suppress RES phagocytosis and reduce IgG synthesis. Patients with bleeding should be transfused with HPA-1a–negative platelets. HPA-1a–positive platelet transfusions are generally ineffective and theoretically may stimulate further antibody production. Patients with PTP appear to be at increased risk for transfusion reactions such as fever, dyspnea, and allergic reactions. Plasma exchange should be considered in patients who do not respond to IVIG.

CHAPTER 134

THROMBOCYTOPENIA CAUSED BY PLATELET DESTRUCTION, HYPERSPLENISM, OR HEMODILUTION

Theodore E. Warkentin

Thrombocytopenia is defined as a platelet count below the lower limit of the normal range (≈150 × 10^9/L). Sometimes an expanded definition of thrombocytopenia is appropriate. For example, an abrupt drop in the platelet count can signify the onset of a platelet-destructive process such as heparin-induced thrombocytopenia (HIT) or bacteremia even if the platelet count remains above 150 × 10^9/L. This is especially relevant in the second or third week after surgery because patients usually have platelet counts that peak at levels two to three times greater than their usual preoperative value (postoperative thrombocytosis).

In the clinical evaluation of a patient with thrombocytopenia, three questions must be asked. First, could the patient have pseudothrombocytopenia? Second, what is the most likely explanation for the thrombocytopenia? And third, what are the risks posed by the causative disorder and the severity of the thrombocytopenia? For example, severe thrombocytopenia caused by drug-dependent antibodies or platelet-reactive autoantibodies is often associated with bleeding. By contrast, thrombocytopenia caused by HIT antibodies or attributable to disseminated intravascular coagulation (DIC) secondary to adenocarcinoma is associated with thrombosis. Often, the underlying cause of the thrombocytopenia (e.g., bacteremia, cancer, cirrhosis), rather than the thrombocytopenia itself, poses the greater risk.

Thrombocytopenia can be caused by any of four general mechanisms: (1) platelet underproduction, (2) increased platelet destruction or consumption, (3) platelet sequestration, and (4) hemodilution. Platelet underproduction usually occurs in association with underproduction of other blood cell lines, which results in bicytopenia or pancytopenia. Thrombocytopenia caused by increased platelet destruction develops when the rate of platelet loss surpasses the ability of the bone marrow (BM) to produce platelets and may be caused by immune or nonimmune mechanisms (Table 134-1). Thrombocytopenia from platelet sequestration is caused by redistribution of platelets from the circulation into an enlarged splenic vascular bed. Hemodilution is characterized by a decrease in the number of platelets, as well as red and white blood cells (WBCs) as a result of the administration of colloids, crystalloids, or platelet-poor blood products.

In the postoperative period, platelet count changes reflect several processes, including initial hemodilution (immediate platelet count decrease) and increased platelet consumption (first 2 to 4 days), at which point the platelet count begins to rise due to increased platelet production; when the platelet count reaches its postoperative peak—usually about 14 days after surgery—platelet production decreases somewhat, and the platelet count returns to baseline (Fig. 134-1).[1] In addition to usual mechanisms, the differential diagnosis of thrombocytopenia in pregnancy includes some unique causes (Table 134-2).

APPROACH TO PATIENTS WITH THROMBOCYTOPENIA

History and Physical Examination

Certain information should be ascertained, including (1) the location and severity of bleeding (if any); (2) the temporal profile of the hemostatic defect (acute, chronic, or relapsing), particularly the temporal relationship with potential proximate triggers (e.g., new drug, recent infection); (3) the presence of symptoms of a secondary illness, such as a neoplasm, infection, or an autoimmune disorder such as systemic lupus erythematosus (SLE); (4) history of recent medication use, alcohol ingestion, or transfusion; (5) presence of risk factors for certain infections, particularly human immunodeficiency virus (HIV) infection or viral hepatitis; and (6) family history of thrombocytopenia (see Chapter 133).

As part of the physical examination, evidence of hemostatic impairment should be sought, as well as secondary causes of thrombocytopenia. The signs of platelet-related bleeding include petechiae and purpura (see Chapter 130). Petechiae typically occur in the dependent regions of the body or on traumatized areas. Spontaneous mucous membrane bleeding (wet purpura), epistaxis, and gastrointestinal bleeding indicate a more serious hemostatic defect. Although petechiae are common in patients whose platelet counts are less than 10 to 20 × 10^9/L, most patients with platelet counts over 50 × 10^9/L have no signs of hemostatic impairment. The physical examination may provide an explanation for the thrombocytopenia. For example, enlarged lymph nodes may indicate a viral infection, such as infectious mononucleosis or HIV infection, or a neoplastic process. An enlarged spleen raises the possibility of hypersplenism.

Timing of Onset and Severity of Thrombocytopenia

Many thrombocytopenic disorders—particularly those involving an immune pathogenesis—exhibit characteristic temporal features that can aid in the diagnosis. For example, if the platelet count begins to fall 5 to 10 days (median, 6-7 days) after starting a new drug or after a blood transfusion and reaches a nadir of less than 20 × 10^9/L a few days later, the diagnosis of drug-induced immune thrombocytopenia (D-ITP) or posttransfusion purpura (PTP), respectively, should be considered (Fig. 134-2).[2] Patients with these disorders typically have mucocutaneous bleeding and are at risk for fatal intracranial hemorrhage.

A similar temporal profile is also characteristic of typical-onset HIT, although there the platelet count only falls below 20 × 10^9/L in 10% of affected patients (see Fig. 134-2); in approximately 80% of patients, the platelet count nadir ranges from 20 to 150 × 10^9/L, and in the remainder, the platelet count nadir never falls below 150 × 10^9/L despite a large reduction in the platelet count. When the platelet count falls abruptly after drug administration, the possibility of rapid-onset thrombocytopenia caused by preexisting drug-dependent antibodies should be considered, as is well described with HIT. Indeed, so-called rapid-onset HIT is the presenting feature of this adverse drug reaction in 25% to 30% of cases. Rapid-onset thrombocytopenia is also a feature of glycoprotein (GP) IIb/IIIa antagonist-induced immune thrombocytopenia.

Occasionally, thrombocytopenia worsens in the first few days after surgery; this can occur in multiorgan system failure (e.g., cardiogenic or septic shock) (see Fig. 134-2). If the platelet count falls to very low levels and is accompanied by microangiopathic hemolysis, the possibility of postoperative thrombotic thrombocytopenic purpura (TTP) should be considered.[3]

Mild to moderate platelet count declines that occur soon after transfusion of blood products are common and can be explained by

Table 134-1 Mechanisms of Platelet Destruction or Consumption

Type of Thrombocytopenia	Specific Example(s)
Immune Mediated	
Autoantibody-mediated platelet destruction by RES	Primary and secondary idiopathic (immune) ITP*
Alloantibody-mediated platelet destruction by RES	NAIT,* PTP,* PAT; alloimmune platelet transfusion refractoriness*
Drug-dependent, antibody-mediated platelet destruction by RES	Drug-induced immune ITP (e.g., quinine) (see Figure 134-5)
Platelet activation by binding of IgG Fc of drug-dependent IgG to platelet FcγIIa receptors	HIT
Non–Immune Mediated	
Platelet activation by thrombin or proinflammatory cytokines	DIC*; septicemia or systemic inflammatory response syndromes
Platelet destruction via ingestion by macrophages (hemophagocytosis)	Infections, certain malignant lymphoproliferative disorders
Platelet destruction through platelet interactions with altered vWF†	TTP,* HUS*
Platelet losses on artificial surfaces	CPB,* use of intravascular catheters
Decreased platelet survival associated with cardiovascular diseases	Congenital and acquired heart disease, cardiomyopathy, PE

CPB, Cardiopulmonary bypass surgery; *DIC,* disseminated intravascular coagulation; *HIT,* heparin-induced thrombocytopenia; *HUS,* hemolytic uremic syndrome; *IgG,* immunoglobulin G; *ITP,* Idiopathic (immune) thrombocytopenic purpura; *NAIT,* Neonatal alloimmune thrombocytopenia; *PAT,* passive alloimmune thrombocytopenia; *PE,* pulmonary embolism; *PTP,* posttransfusion purpura; *RES,* reticuloendothelial system; *TTP,* thrombotic thrombocytopenic purpura; *vWF,* von Willebrand factor.
*See Chapter 133 for a discussion of thrombocytopenia in these disorders.
†Although platelet destruction is not directly caused by antibodies, immune mechanisms can explain altered vWF (e.g., autoimmune clearance of vWF-cleaving metalloprotease).

Table 134-2 Differential Diagnosis of Thrombocytopenia in Pregnancy

- Incidental thrombocytopenia of pregnancy (gestational thrombocytopenia)
- Preeclampsia or eclampsia*
- DIC secondary to:
 - Abruptio placentae
 - Endometritis
 - Amniotic fluid embolism
 - Retained fetus
 - Preeclampsia or eclampsia*
- Peripartum or postpartum thrombotic microangiopathy
 - TTP
 - HUS

DIC, Disseminated intravascular coagulation; *HUS,* hemolytic uremic syndrome; *TTP,* thrombotic thrombocytopenic purpura.
*Preeclampsia or eclampsia usually is not associated with overt DIC.

hemodilution; however, a marked platelet count fall after transfusion may be the result of passive alloimmune thrombocytopenia (PAT) or sepsis because of contaminated blood products (see Fig. 134-2).

Other characteristic temporal features of thrombocytopenia include postenterohemorrhagic *Escherichia coli*–associated hemolytic uremic syndrome (HUS; thrombocytopenia and microangiopathic hemolysis that begin approximately 1 week after a prodromal diarrheal illness) and fungemia-associated thrombocytopenia (onset, 1-3 weeks after complex illness involving indwelling catheters and broad-spectrum antibiotic usage). In contrast, thrombocytopenia of insidious onset that progresses over several years suggests chronic liver disease, with evolution to progressive portal hypertension and associated splenomegaly (e.g., cirrhosis secondary to alcohol or hepatitis C) or a slowly progressive BM disorder (e.g., myelodysplasia).

Laboratory Evaluation

Laboratory evaluation of patients with thrombocytopenia is summarized in Table 134-3 (also see Chapter 131). The blood film is examined to exclude pseudothrombocytopenia, which is characterized by in vitro platelet clumping. This phenomenon, which is evident in approximately one in 1000 blood samples, is most often caused by naturally occurring GPIIb/IIIa ($\alpha_{IIb}\beta_3$)-reactive autoantibodies that induce aggregation of platelets in the presence of the calcium-chelating anticoagulant ethylenediamine tetraacetic acid (EDTA). Because the platelet aggregates are not counted by the electronic particle counter, the automated platelet count appears falsely low. The correct platelet count usually can be determined by collecting the blood into sodium citrate or heparin or by performing the count on nonanticoagulated finger prick samples; maintaining the blood sample at 37°C often attenuates platelet clumping. EDTA-dependent pseudothrombocytopenia has no pathologic significance other than potentially placing a patient in jeopardy for inappropriate treatment of thrombocytopenia that does not exist. A much less common (one in 10,000 blood samples) antibody-mediated pseudothrombocytopenic disorder is platelet satellitism, in which rosette-like clusters of platelets surround neutrophils. This entity is produced by immunoglobulin G (IgG) antibodies that recognize EDTA-induced cryptic epitopes on both platelet GPIIb/IIIa and neutrophil FcγIII receptors.

Bone marrow examination can be helpful for assessment of platelet production, particularly if megakaryocytes are reduced in number or abnormal in appearance. Examination of the BM can be diagnostic in some disorders (e.g., leukemia, metastatic tumor, Gaucher disease, megaloblastic anemia).

Elevated platelet-associated IgG (PAIgG) can be detected in patients with either immune or nonimmune thrombocytopenia; therefore, this assay is not useful diagnostically. In contrast, GP-specific platelet antibody assays, such as the monoclonal antibody immobilization of platelet antigens (MAIPA) assay or antigen capture enzyme immunoassay, are relatively specific for detection of autoimmune thrombocytopenic disorders. These assays can also be adapted for detection of drug-dependent GP-reactive antibodies.

When the mechanism of chronic thrombocytopenia is unclear, an autologous platelet survival study using ^{111}In-labeled platelets may be informative. Three patterns can be seen: (1) normal platelet survival and recovery (underproduction), (2) marked reduction in the platelet life span (increased destruction), and (3) reduced recovery but a normal or near-normal life span (sequestration). However, platelet survival studies are rarely performed in practice.

Therapy

The risk of bleeding in patients with thrombocytopenia can be reduced by avoiding drugs that impair hemostasis (e.g., alcohol, antiplatelet agents, anticoagulants) and invasive procedures (e.g., intramuscular injections). If drug-induced thrombocytopenia is suspected, as many medications as possible should be stopped. Life-threatening bleeding episodes should be treated with platelet transfusion regardless of the mechanism of the thrombocytopenia.

The underlying cause and anticipated natural history of the thrombocytopenic disorder influence the decision about prophylactic platelet transfusion. As a general rule, patients with chronic thrombocytopenic disorders characterized by increased platelet destruction (e.g., chronic ITP) or chronic underproduction (e.g., aplastic anemia

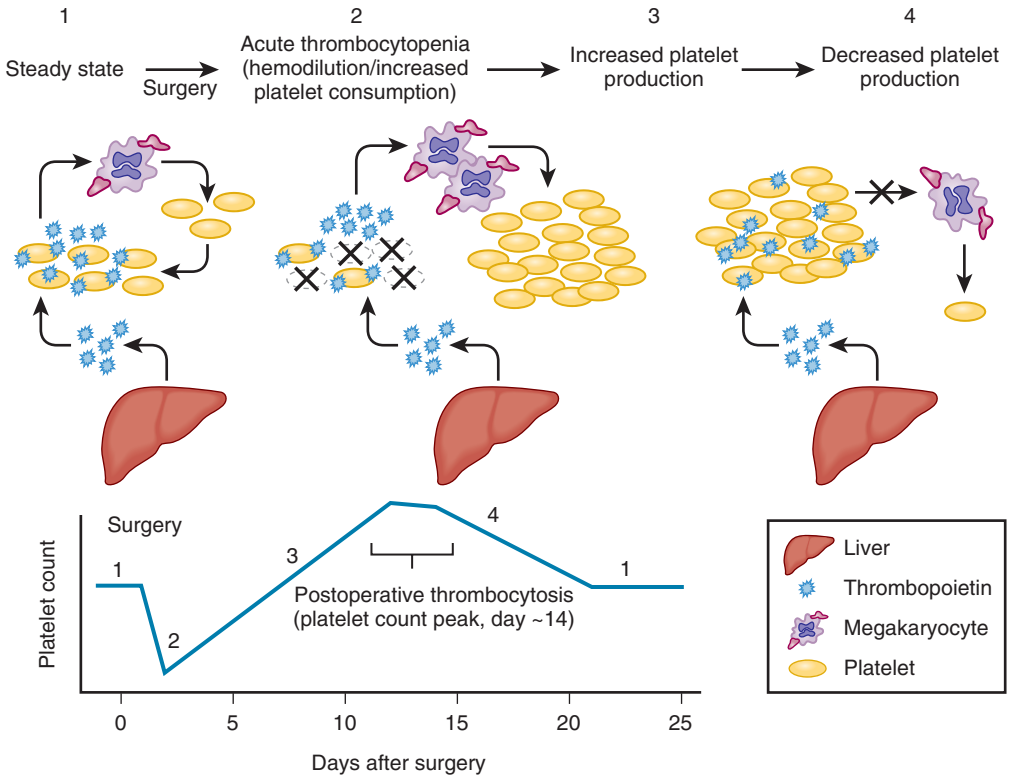

Figure 134-1 POSTSURGERY PLATELET COUNT CHANGES. Initial platelet count declines result from hemodilution and increased platelet consumption, with the platelet count nadir occurring between days 1 to 4 (median, day 2). There is constitutive production of thrombopoietin (TPO) by the liver. TPO binds to platelets and megakaryocytes via a specific receptor (c-Mpl, not shown), and receptor-bound TPO is removed from circulation and degraded. The level of circulating TPO is thus inversely related to the mass of platelets and megakaryocytes. In early postsurgery thrombocytopenia, fewer TPO binding sites are available, resulting in high free TPO levels, which stimulates megakaryocyte proliferation and differentiation and leads to increased platelet production. With subsequent thrombocytosis, the high platelet mass acts as a "sink" for removing TPO, with decreased stimulus for platelet production. Thus, after acute postsurgery thrombocytopenia, TPO levels rise about twofold, leading to increased platelet production that begins on days 2 to 4, with resulting thrombocytosis that generally peaks at approximately day 14 (postoperative thrombocytosis) and returns to baseline by about day 21. *(Reprinted, with modifications, with permission, from Arnold DM, Warkentin TE: Thrombocytopenia and thrombocytosis. In Wilson WC, Grande CM, Hoyt DB, editors:* Trauma: Critical care, *vol 2. New York, 2007, Informa Healthcare, p 983.)*

or myelodysplasia) can tolerate long periods of severe thrombocytopenia without major bleeding. In addition, prophylactic platelet transfusions can trigger alloimmunization against human leukocyte antigen (HLA) or platelet antigens, thereby jeopardizing future therapeutic platelet transfusions. Consequently, prophylactic platelet transfusions are seldom indicated for such patients except when they are at risk of bleeding because of trauma or major surgery. When platelets are given, the platelet count should be maintained above 50×10^9/L. Invasive procedures such as thoracentesis, paracentesis, and liver biopsy are not usually associated with excess bleeding if the platelet count is greater than 50×10^9/L.

Prophylactic platelet transfusions should not be given to patients with strongly suspected or confirmed HIT, TTP, or HUS because they may exacerbate platelet-mediated thrombotic complications, and, particularly with HIT, mucocutaneous bleeding is uncommon. However, bleeding in the setting of severe thrombocytopenia may justify platelet transfusion even in these disorders.

ANATOMY AND PHYSIOLOGY

The Spleen: Anatomy and Function

The spleen is a small, well-perfused organ that receives about 5% of the total cardiac output. In adults, the spleen weighs between 150 to 200 g and measures approximately 11 cm in length.

The anatomy of the spleen is uniquely suited for its function; progressive branching of the splenic artery into trabecular and central arteries helps separate the plasma from the cellular elements (see Chapter 162). The central arteries arise perpendicularly from the trabecular arteries and skim the plasma layer from the cells. Soluble antigens in the plasma are delivered to the white pulp, where phagocytic cells process them and antibody production is initiated.

A cell-rich, hemoconcentrated fraction of the blood is delivered to the red pulp. Some of this blood flows directly to the splenic veins (the closed system), but most moves into the splenic cords (the open system). Here, the cellular elements percolate through a meshwork of reticulum fibers, reticuloendothelial cells, and supporting cells to reach the splenic sinuses. The cells enter the sinuses by passing through narrow fenestrations in the basement membrane of the endothelial cells lining the sinuses. The blood exits through the splenic vein into the portal system. Because the veins in the portal system lack valves, any increase in portal pressure is transmitted to the splenic microcirculation.

The spleen plays a number of important roles. It is the largest lymphoid organ in the body and contributes to host defense by clearing microorganisms and antibody-coated cells. The spleen also is important for antibody synthesis, especially antibodies directed against soluble antigens. The filtering function of the spleen includes (1) culling (removal of damaged or senescent cells and bacteria), (2) pitting (removal of red blood cell [RBC] inclusion bodies or parasites), and (3) remodeling (reticulocyte sequestration and

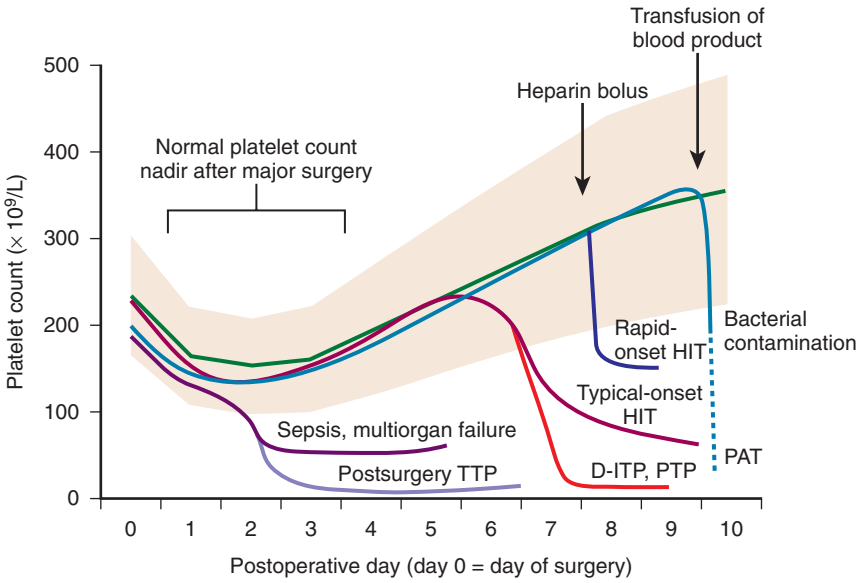

Figure 134-2 TIMING OF ONSET AND SEVERITY OF THROMBOCYTOPENIA: IMPLICATIONS FOR DIFFERENTIAL DIAGNOSIS. The usual postoperative platelet count nadir is seen between postoperative days 1 to 3 (inclusive). Early and progressive platelet count declines often reflect severe postoperative complications such as sepsis and multiorgan failure; severe thrombocytopenia can (rarely) indicate postsurgery thrombotic thrombocytopenic purpura (TTP). Thrombocytopenic disorders that begin approximately 1 week after surgery are often immune mediated: moderate thrombocytopenia can indicate heparin-induced thrombocytopenia (HIT), both "typical onset" or (if heparin is not being given) "delayed onset"; very severe thrombocytopenia can indicate drug-induced immune thrombocytopenic purpura (D-ITP) or (rarely) posttransfusion purpura (PTP). An abrupt decline in platelet count after receiving a heparin bolus in a patient who has received heparin within the past 7 to 100 days can indicate "rapid-onset" HIT; thrombocytopenia that begins abruptly after transfusion of a blood product can indicate sepsis from bacterial contamination or (rarely) passive alloimmune thrombocytopenia (PAT) caused by transfusion of platelet-reactive alloantibodies. *(Reprinted, with permission, from Greinacher A, Warkentin TE: Acquired non-immune thrombocytopenia. In: Marder VJ, Aird WC, Bennett JS, et al, editors:* Hemostasis and thrombosis: Basic principles and clinical practice, *ed 6. Philadelphia, 2012, Lippincott Williams & Wilkins, in press.)*

maturation). The spleen also acts as a reservoir of platelets (accommodating about one-third of the platelet mass in normal individuals). By contrast, the human spleen contains less than 2% of the total red RBC mass, although in some animals (dogs and cats), the spleen is a much more important RBC reservoir.

Physiologic Platelet Sequestration

Radiolabeled platelet studies have shown that approximately 30% of the total platelet mass exists as a freely exchangeable pool in the spleen. Because the normal platelet life span is 9 to 10 days, platelets spend approximately one-third of their lives, or 3 days, within the spleen. In patients with hypersplenism, as many as 90% of the platelets can be found in the spleen.

After labeled platelets are injected, accumulation is apparent in both the liver and the spleen. An initial, irreversible phase of hepatic uptake occurs. This equilibrates during the first 5 minutes and may reflect hepatic clearance of platelets damaged during the labeling procedure. Simultaneously, there is a slow increase in activity over the spleen that peaks in about 20 minutes. Splenic platelet uptake is thus dependent on input (spleen blood flow) and output (clearance).

The splenic platelet pool size can be decreased and the platelet count increased with intravenous infusions of epinephrine in normal persons and in patients with splenomegaly. By contrast, isoprenaline increases the pool size. Splenic blood flow increases with increasing spleen size, although perfusion (flow per unit of tissue volume) falls. Blood flow can be increased in some inflammatory disorders (e.g., SLE) without an increase in spleen size. A marked increase or decrease in splenic perfusion alters the proportion of platelets within the spleen.

Fig. 134-3 shows why approximately 30% of the platelets are normally present in the spleen.[1] Because about 5% of cardiac output goes to the spleen and because the average splenic transit time (i.e., the time for the platelet to pass through the spleen) is approximately 10 minutes—compared with the usual average time of 1 minute for a platelet to make a complete circulatory pass—the proportion of platelets within the spleen is approximately one-third (i.e., 5% × 10 min : 95% × 1 min, or a ratio of 50:95, or ≈1 : 2). With hypersplenism, the splenic blood flow can increase up to fivefold (i.e., from 5% to 25% of total blood flow). Thus, even without an increase in splenic transit time, 70% or more of the platelets can be exchangeably sequestered within the spleen.

The most important determinant of the splenic platelet pool is the spleen size. The measurement of spleen size can thus be helpful in predicting the degree of thrombocytopenia expected from excess platelet pooling in the spleen. For example, if the splenic platelet pool is 90% (i.e., 10% outside the spleen), the platelet count will be reduced by a factor of 7 (because normally, 70% of platelets lie outside the spleen). Consequently, and as a general rule, even if the spleen is massively enlarged, severe thrombocytopenia ($<20 \times 10^9$/L) is rarely seen. On the other hand, mild thrombocytopenia may be explained by mild splenomegaly that may not be detectible on physical examination but can be seen with imaging studies.

Table 134-3 Laboratory Tests Used to Investigate a Patient With Thrombocytopenia

Test	Rationale
Common Tests	
CBC	Isolated thrombocytopenia usually is caused by platelet destruction, but involvement of all cell lines suggests underproduction or sequestration
Examination of the blood film	Pseudothrombocytopenia (platelet clumps) Toxic changes and granulocyte "left shift" suggest septicemia Atypical lymphocytes suggest viral infection RBC fragments suggest TTP or HUS Parasites (e.g., in malaria) White cell inclusions suggest hereditary macrothrombocytopenia
Blood cultures	Bacteremia, fungemia
ANA test	Systemic lupus erythematosus
Direct antiglobulin test	Exclude immune hemolysis accompanying ITP (Evans syndrome)
Coagulation assays	
aPTT, PT (INR), thrombin time, fibrinogen, D-dimer assay	DIC
LA assay (nonspecific inhibitor), anticardiolipin and anti-β_2-glycoprotein I assays	aPL antibody syndrome
Serum protein electrophoresis; IgG, IgM, IgA levels	ITP associated with lymphoproliferative disorder (monoclonal); hypersplenism associated with chronic hepatitis (polyclonal)
HIV serologic studies	HIV-associated thrombocytopenia
BM aspiration, biopsy	Assess megakaryocyte numbers and morphology; exclude primary BM disorder
Specialized Tests	
GP-specific platelet antibody assays (e.g., MAIPA)	Relatively specific assay for primary and secondary ITP
Drug-dependent increase in platelet-associated IgG	Specific assay for D-ITP
Drug-dependent platelet activation test (e.g., platelet serotonin release assay) or PF4–heparin (or PF4-polyanion) ELISA	HIT
Radionuclide platelet lifespan study with imaging (e.g., ^{111}In platelet survival study)	Define the mechanism of thrombocytopenia; identify an "accessory" spleen postsplenectomy

ANA, Antinuclear antibody; *aPL,* antiphospholipid; *aPTT,* activated partial thromboplastin time; *CBC,* complete blood count; *DIC,* disseminated intravascular coagulation; *D-ITP,* drug-induced immune thrombocytopenia; *ELISA,* enzyme-linked immunosorbent assay; *GP,* glycoprotein; *HIT,* heparin-induced thrombocytopenia; *HIV,* human immunodeficiency virus; *HUS,* hemolytic uremic syndrome; *IgG,* immunoglobulin G; *INR,* international normalized ratio; *ITP,* idiopathic (immune) thrombocytopenic purpura; *LA,* lupus anticoagulant; *MAIPA,* monoclonal antibody immobilization of platelet antigens; *PF4,* platelet factor 4; *PT,* prothrombin time; *RBC,* red blood cell; *TTP,* thrombotic thrombocytopenic purpura.

PATHOLOGIC PLATELET SEQUESTRATION: HYPERSPLENISM

Definition

Hypersplenism is a syndrome characterized by splenomegaly and any or all of the following cytopenias: anemia, leukopenia, or thrombocytopenia. Implicit in the definition is that the cytopenias will correct after splenectomy. Although splenomegaly is almost always present in hypersplenism, many patients with splenomegaly do not have hypersplenism. The hypersplenism usually is the result of an identifiable pathological process, but rarely, the cause of the splenomegaly remains elusive, and the hypersplenism is termed *primary*.

Pathogenesis

A list of disorders producing splenomegaly and hypersplenism is presented in Table 134-4. An increase in the size of the spleen can be caused by several mechanisms. Increased workload of the spleen can be caused by immunologic stress (infection, inflammation, or an autoimmune disorder) or by increased RBC removal (RBC membrane disorders, hemoglobinopathies). Portal hypertension also increases the size of the spleen, producing congestive splenomegaly. Benign and malignant infiltrative disorders may increase splenic size (infiltrative splenomegaly) and cause hypersplenism. Some of these disorders produce thrombocytopenia by more than just hypersplenism (e.g., BM infiltration with tumor, immune-mediated platelet clearance). Thus the demonstration of an enlarged spleen does not necessarily mean that the cytopenias are caused solely by hypersplenism.

Thrombocytopenia of hypersplenism is caused primarily by increased splenic platelet pooling. A massively enlarged spleen can hold more than 90% of the total platelet mass. In the absence of altered platelet production, the total body platelet mass usually is normal, and the platelet life span is near normal. Usually, the splenic transit time remains normal (≈10 minutes), but the absolute number of platelets retained within the enlarged spleen is increased. All of these platelets remain part of the exchangeable pool. In hypersplenism, the thrombocytopenia is moderately severe (platelet counts of 50×10^9/L to 150×10^9/L). Severe thrombocytopenia ($<20 \times 10^9$/L) suggests another diagnosis. Therefore, it is unusual for patients with hypersplenism to have evidence of hemostatic impairment attributable to thrombocytopenia or to need specific interventions to raise the platelet count. Plasma volume expansion occurs in hypersplenism, but hemodilution plays a relatively minor role in the thrombocytopenia. In some patients with advanced liver disease, impaired hepatic production of thrombopoietin may contribute to thrombocytopenia in addition to hypersplenism.

The neutropenia of hypersplenism is caused by an increase in the marginated granulocyte pool, a portion of which is located in the spleen. The neutropenia of hypersplenism usually is asymptomatic.

Diagnosis

Thrombocytopenia is likely to be caused by hypersplenism when (1) splenomegaly is present, (2) the thrombocytopenia is mild to moderate in severity, (3) moderately reduced neutrophil and low-normal hemoglobin levels are found, and (4) no or minimal evidence for impaired hematopoiesis is observed on BM examination. Ultrasonography, computed tomography, and radionuclide imaging are of comparable sensitivity for documenting splenomegaly, and an imaging study should be performed if splenomegaly is not evident on physical examination. The mean platelet volume often is slightly decreased in hypersplenism, but this finding is not sufficiently specific to be diagnostically useful. An ^{111}In-labeled platelet survival study can be diagnostic of hypersplenism, demonstrating reduced platelet recovery and a normal platelet life span. Determining the cause of the splenomegaly usually is the most important issue.

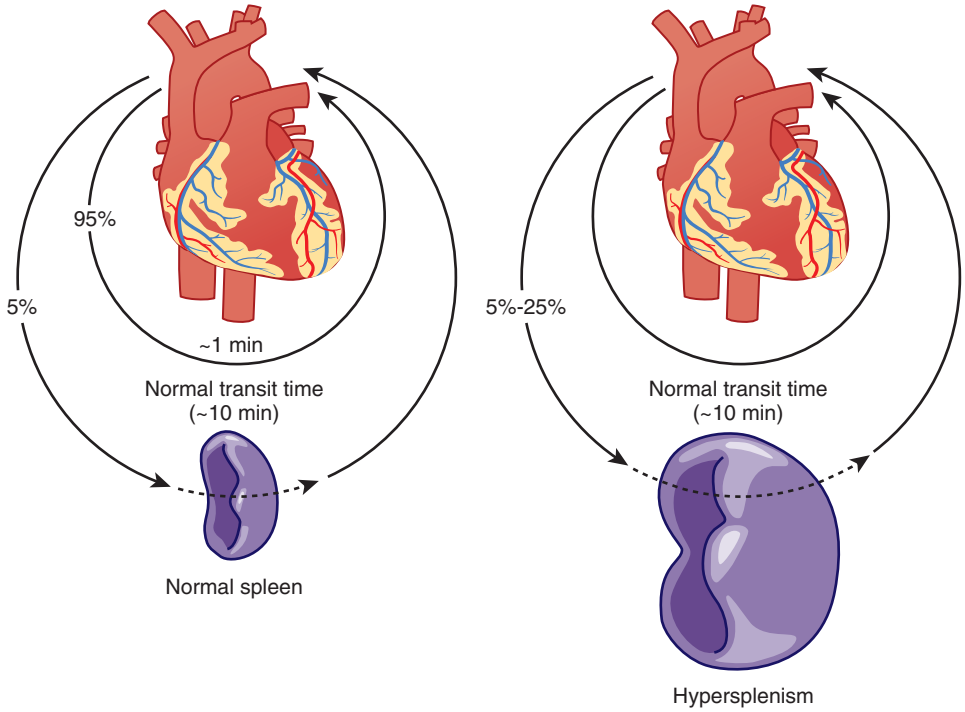

Figure 134-3 PHYSIOLOGIC AND PATHOLOGIC PLATELET SPLENIC SEQUESTRATION. Normally, about 5% of cardiac output is to the spleen; however, a platelet that enters the spleen spends about 10 minutes there (splenic transit time =10 min). In contrast, it usually takes only about 1 minute for a platelet to make a circulatory pass elsewhere. Thus about one-third of the platelets at any one time are located within the spleen: (5% × 10 min):(95% × 1 min), or an approximate 1 : 2 ratio. In hypersplenism, the splenic blood flow can increase by a factor of 5, that is, from 5% to 25% of total blood flow per minute. Thus, even without increase in splenic transit time, up to 70% or more of the platelets can be exchangeably sequestered within the spleen. *(From Arnold DM, Warkentin TE: Thrombocytopenia and thrombocytosis. In: Wilson WC, Grande CM, Hoyt DB, editors:* Trauma: Critical care, *vol. 2. New York, 2007, Informa Healthcare USA, p 983.)*

Therapy

Several maneuvers can improve or correct the cytopenias attributable to hypersplenism, including total or partial splenectomy; partial splenic embolization; and, in patients with congestive splenomegaly, surgical or transjugular intrahepatic portosystemic shunting. However, cytopenias secondary to hypersplenism thrombocytopenia in particular are almost never of sufficient severity to justify treatment. Consequently, the decision to perform one of these interventions usually depends on other considerations. For example, splenectomy should be considered for relief of pain or early satiety associated with massive splenomegaly (e.g., in myelo- or lymphoproliferative disorders) or for splenomegaly of unknown origin (for investigation of possible splenic lymphoma).

Short-term complications from splenectomy include infections, bleeding, and thromboembolism. The major long-term risk associated with splenectomy is overwhelming septicemia; this risk can be reduced by vaccination. All patients should be vaccinated against pneumococci, meningococci, and *Haemophilus* spp. at least 2 weeks before elective splenectomy. Moreover, "booster" doses of pneumococcus and meningococcus vaccines are recommended after 5 years.[4,5] Splenectomy for congestive hypersplenism in the setting of portal hypertension is associated with high morbidity and mortality rates. Splenectomy also is associated with high morbidity (50%) and mortality (10%-15%) rates in myeloid metaplasia and does not alter the natural history of this disorder. Thus splenectomy usually is performed for palliation of intractable symptoms.

Splenectomy in Gaucher disease usually corrects the cytopenias, relieves abdominal discomfort, and improves growth in children. Partial, rather than total, splenectomy has been used in an attempt to avoid shifting the deposition of glucocerebroside from the spleen to the bones. Often, however, splenomegaly and hypersplenism recur after partial splenectomy. Enzyme replacement therapy can reduce the morbidity from hypersplenism (see Chapter 162).

DRUG-INDUCED THROMBOCYTOPENIC SYNDROMES

Many drugs can cause thrombocytopenia. Some drugs (e.g., anticancer chemotherapeutic agents, valproic acid) cause dose-dependent thrombocytopenia, generally through myelosuppressive mechanisms. An important disorder encountered by hematologists is unexpected thrombocytopenia caused by immunologic (idiosyncratic) mechanisms.[6,7] The frequency of these reactions varies considerably among drugs and ranges from very rare (<1 in 10,000) for commonly used drugs such as acetaminophen, indomethacin, naproxen, quinine or quinidine, and trimethoprim–sulfamethoxazole (TMP-SMX) to common (1%-5%) for other drugs such as gold and unfractionated heparin (UFH).

Immunologic drug-induced thrombocytopenia can occur through different mechanisms (Fig. 134-4). For example, thrombocytopenia can occur when the Fab terminus of the pathogenic IgG binds to a complex composed of drug (or drug metabolite) and a platelet membrane component (typically, platelet GPIIb/IIIa or GPIb/IX/V). The Fc portions of the pathogenic IgG molecules do not bind to platelets but interact with Fc receptors on phagocytic cells of the reticuloendothelial system, which ingest the platelets, leading to accelerated platelet clearance. Severe thrombocytopenia (platelet counts <20 × 10^9/L) typically is observed (see Fig. 135-3 in Chapter 135). This mechanism is exemplified by quinine- and quinidine-induced thrombocytopenia. Sometimes the Fab terminus binds to a neoepitope on platelet GPIIb/IIIa induced by the drug, and the drug itself is not

part of the neoepitope. This mechanism is exemplified by the GPIIb/IIIa receptor antagonist eptifibatide. Rarely, some drugs may induce the formation of typical platelet GP-reactive autoantibodies (e.g., gold-induced thrombocytopenia or acute ITP after administration of certain vaccines).

Another distinct form of drug-induced thrombocytopenia is exemplified by HIT (see Chapter 135). In this disorder, the Fab portion of the pathogenic IgG binds to platelet factor 4 (PF4), an α-granule protein that is immunogenic when complexed to heparin or certain other polyanions. The Fc portions of the IgG molecules bind to platelet FcγIIa receptors, initiating intense platelet activation (see Fig. 134-4). Perhaps because HIT is a platelet activation syndrome or because of the relatively low number of HIT antibodies that bind to platelet surfaces, the thrombocytopenia is typically mild to moderate rather than severe (see Fig. 135-3 in Chapter 135).

Finally, drug-induced antibodies can explain thrombocytopenia by unusual mechanisms. For example, the antiplatelet agents ticlopidine and clopidogrel are rare causes of TTP, possibly because drug-dependent antibodies form against the von Willebrand factor (vWF)–cleaving metalloprotease ADAMTS13 (a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13). Quinine is another cause of microangiopathic hemolysis, although in this situation, the terms *HUS* and *DIC* are often used, reflecting the prominent renal failure or coagulation abnormalities, respectively, observed in some affected patients.

DRUG-INDUCED IMMUNE THROMBOCYTOPENIA

A large number of drugs can cause a syndrome that mimics acute ITP (D-ITP); however, there are relatively few drugs for which causation is well established on both clinical and serologic grounds (Fig. 134-5).[8,9] Typically, severe thrombocytopenia (platelet count usually $<20 \times 109/L$), together with petechiae and purpura, develops within approximately 1 week (although occasionally much longer) after initiation of therapy with the responsible drug. D-ITP is much less common than HIT. For example, a relatively "common" cause of this syndrome is trimethoprim-sulfamethoxazole (co-trimoxazole), even though it occurs in only approximately one in 25,000 patients who receive this drug combination.

Important exceptions to these generalizations occur with immune thrombocytopenia that results from GPIIb/IIIa receptor antagonists; these reactions are relatively common (affecting about 0.5%-1% of patients) and usually occur within hours of first use as a result of preexisting, naturally occurring antibodies. Another exception is carbimazole-induced thrombocytopenia, in which mild thrombocytopenia is explained by the presence of relatively small quantities of the platelet GP target (platelet endothelial cell adhesion molecule-1 [PECAM-1]) on the platelet surface. Besides the atypical immune-mediated syndromes of HIT and GPIIb/IIIa antagonist thrombocytopenia, the most common drugs (in absolute terms) implicated in the causation of classic D-ITP syndrome are quinine (outpatients) and vancomycin (inpatients).[10]

Pathogenesis

Drug-dependent binding of the Fab component of IgG to platelet GP leads to platelet destruction. This occurs because the IgG-sensitized platelets are recognized by Fc receptors of phagocytic cells. For quinine- and quinidine-induced immune thrombocytopenia, both the GPIIb/IIIa and GPIb/IX/V complexes have been implicated as targets for the drug-dependent IgG (see Fig. 134-4). By contrast, for sulfa antibiotic- and naproxen-induced immune thrombocytopenia, the GPIIb/IIIa complex is predominantly involved. Sometimes, drug metabolites form the antigen rather than the parent drug. A trimolecular complex is formed among IgG Fab, the drug (or metabolite), and the platelet GP. In contrast to HIT, platelet Fc receptors are not involved in D-ITP pathogenesis. Drug-dependent IgG binding

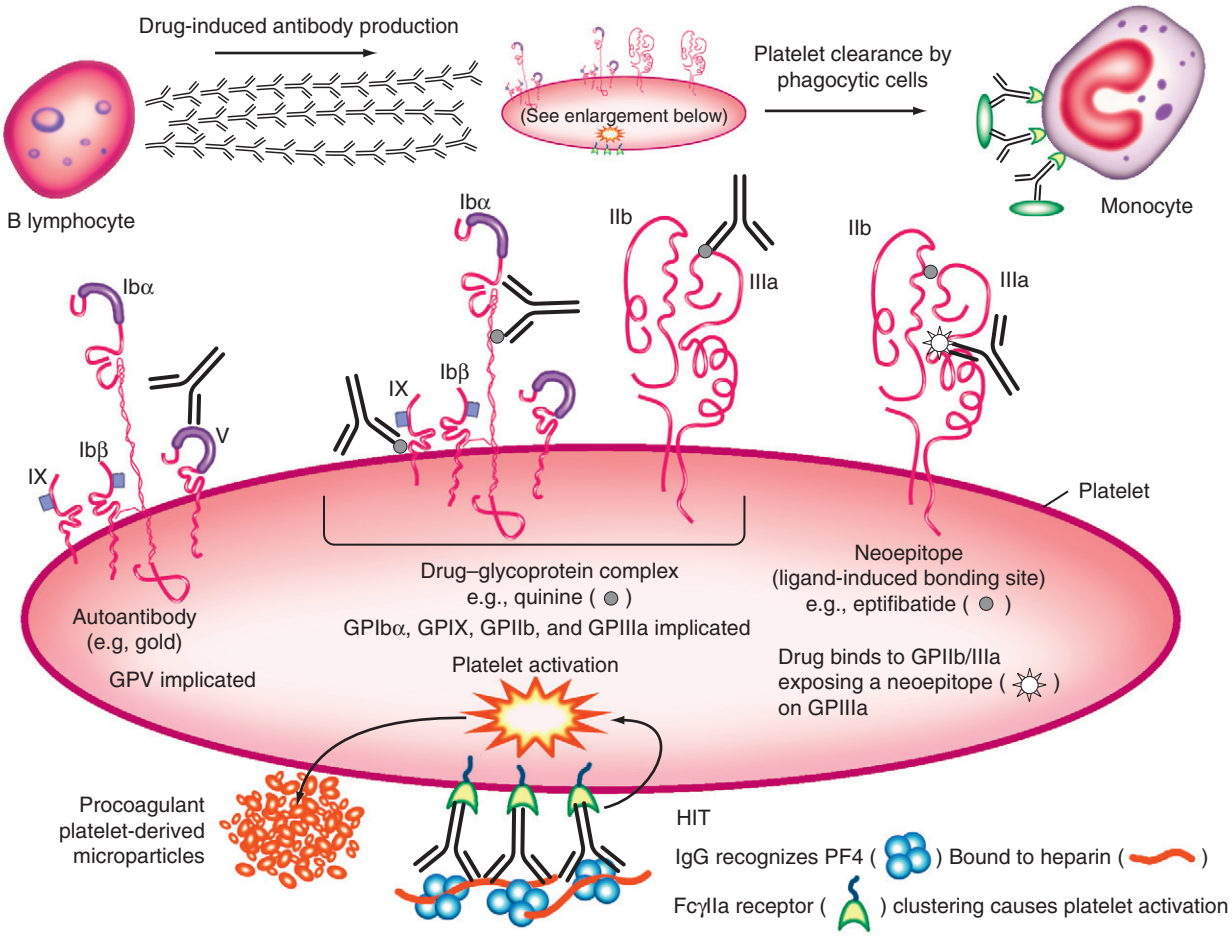

Figure 134-4 MECHANISMS OF DRUG-INDUCED IMMUNE THROMBOCYTOPENIA. Four immune thrombocytopenic syndromes are illustrated. On the *bottom* of the schematic platelet, heparin-induced thrombocytopenia (HIT) is illustrated, indicating that immunoglobulin G (IgG) antibodies bind to complexes of platelet factor 4 (PF4) and heparin, with the Fc regions of the antibodies binding to the platelet FcγIIa receptors, resulting in platelet activation (including generation of procoagulant, platelet-derived microparticles). On the *top* of the schematic platelet, three mechanisms are illustrated that lead to increased platelet clearance by phagocytic cells. From left to right, these are (1) autoantibody-induced immune thrombocytopenia (e.g., gold-induced antiglycoprotein V [GPV] antibodies). (2) drug-dependent antibodies reactive against drug (or drug metabolite)–platelet glycoprotein complex(es) (e.g., quinine-induced thrombocytopenia in which drug-dependent antibodies against GPIbα, GPIX, GPIIb, and GPIIIa have been implicated, resulting in an antibody/drug/glycoprotein ternary complex), and (3) antibodies against neoepitope(s) formed in the presence of a drug (e.g., eptifibatide-induced immune thrombocytopenia caused by formation of ligand-induced binding site elsewhere on the GPIIb/IIIa complex after eptifibatide binding). Note that preexisting (naturally-occurring) antibodies can explain abrupt-onset thrombocytopenia in a patient receiving eptifibatide for the first time.

is remarkably heterogeneous with respect to binding affinity, number of binding sites per platelet, and the range of drug concentrations required. A recent study of quinine-induced immune thrombocytopenia identified two different types of antibodies: quinine-dependent antibodies that bound to platelets in the presence of drug and quinine-specific antibodies that reacted with quinine-conjugated albumin.[11] The pathophysiological implications of this latter group of antibodies remains unclear.

The fundamental mechanism that accounts for antibody formation in a small proportion of patients is unknown. One group has proposed that drug-dependent platelet-reactive antibodies are derived from a pool of naturally occurring autoantibodies with inherently weak (nonpathologic) affinity for certain platelet membrane GPs (Fig. 134-6).[6,11] However, if a certain drug is able to enhance antibody–antigen interaction, and if B cells expressing such antibodies are induced to proliferate and undergo affinity maturation in such a patient, the resulting antibody can destroy the platelets in the presence of the drug.

Clinical Features

Patients with D-ITP typically present with petechiae, purpura, and severe thrombocytopenia (platelet count often $<20 \times 10^9$/L). Systemic symptoms, such as fever and chills, may occur in patients with abrupt-onset thrombocytopenia. Usually, the thrombocytopenia becomes clinically apparent 1 to 2 weeks after initiation of the drug, but the thrombocytopenia can start after a patient has been taking a drug for several years. Typically, the platelet count begins to rise in a few days after discontinuation of the implicated drug, but occasionally several weeks are required for recovery, possibly because of the generation of drug-independent IgG (platelet autoantibodies).

Sometimes drug exposure is relatively obscure. Among outpatients, the physician needs to inquire about potential exposure to quinine. Quinine is widely available—as an ingredient in tonic water, for example, as an additive to street drugs, and in some countries as therapy for leg cramps. Vancomycin is a relatively common cause of D-ITP in hospitalized inpatients; most often this results from the

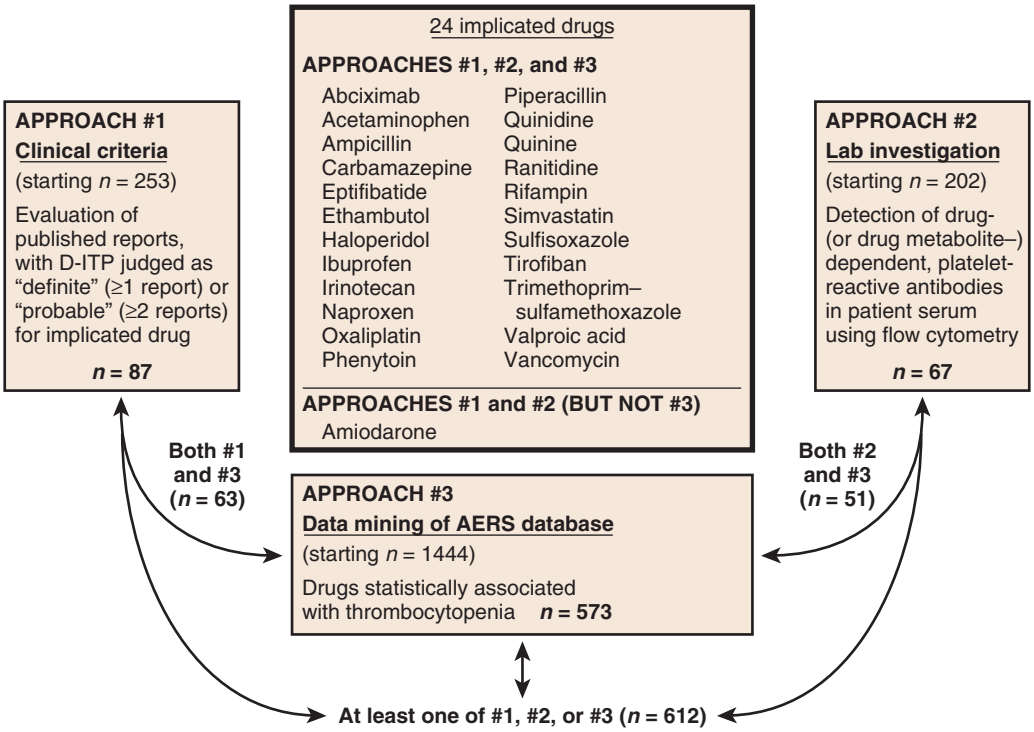

Figure 134-5 TWO DOZEN DRUGS WITH STRONG EVIDENCE FOR CAUSING DRUG-INDUCED IMMUNE THROMBOCYTOPENIA (D-ITP) SYNDROME. Three different approaches were used to adjudicate drugs as possibly causing D-ITP. The *central box* lists the 23 agents identified using all three methods plus one drug (amiodarone) implicated by only the first two methods. The categories "Both #1 & #3" and "Both #2 and #3" include the 23 patients who were identified using all three approaches. The numbers of drugs implicated by only one of the three approaches were 23, 15, and 482 for approaches #1, #2, and #3, respectively. *AERS,* Adverse Event Reporting System. *(Adapted from Warkentin TE, Anderson JAM: DITP causation: 3 methods better than 1?* Blood *116:2002, 2010.)*

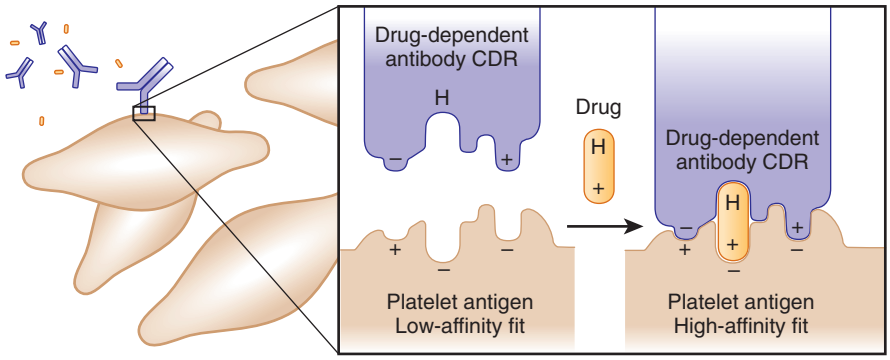

Figure 134-6 MODEL FOR BINDING OF DRUG-DEPENDENT ANTIBODIES TO PLATELET GLYCOPROTEIN (GP) EPITOPES. Antibodies capable of causing drug-dependent thrombocytopenia react weakly with an epitope on a target GP. The binding affinity (K_A) for this interaction is too low to allow a sufficient number of antibody molecules to bind in the absence of the drug ("low-affinity fit"). The drug contains structural elements that are complementary to a negatively charged site on the GP and a hydrophobic site (H) on the complementarity-determining region (CDR) of the antibody. The drug interacts with these sites to improve the fit between the two proteins, increasing the K_A to a value that permits binding to occur at levels of antibody, antigen, and drug achieved in the circulation after ingestion of the drug ("high-affinity fit"). *(From Aster RH, Bougie DW: Drug-induced immune thrombocytopenia.* N Engl J Med *357:580, 2007. Copyright Massachusetts Medical Society. Reprinted with permission.)*

usual intravenous administration, but some reports have implicated exposure via orthopedic cement or with peritoneal administration of vancomycin.

Rarely, distinct drug-dependent IgG molecules destroy RBCs or WBCs in addition to platelets. For example, both platelet- and leukocyte-reactive quinidine-dependent IgG molecules have been detected in a patient with quinidine-induced bicytopenia. Sometimes the immune process is directed against a pluripotent hematopoietic stem cell, resulting in pancytopenia accompanied by BM aplasia or hypoplasia (e.g., gold-, carbamazepine-, or quinidine-induced pancytopenia). A BM aspirate should be performed in patients with suspected drug-induced bicytopenia or pancytopenia because a hypoplastic BM may be indicative of drug-induced aplastic anemia.

Diagnosis

A high index of clinical suspicion is required to make the diagnosis. Moreover, clinicians need to evaluate which drug (often among several that the patient is receiving) is most likely to explain a diagnosis of D-ITP.[8,12-14] The clinician should focus on drugs that have been started 5 to 10 days before the onset of the platelet count decrease (Fig. 134-7, *A*). Also, with drugs such as quinine, in which there may be intermittent exposure (e.g., consumption of "gin and tonic"), a very recent exposure (previous 1 or 2 days) usually explains the abrupt onset of symptomatic thrombocytopenia.

After the physician has identified one or more potential agents, the next step is to determine whether these drugs have previously been implicated as causes of D-ITP. The box Search Strategies When Investigating Patient With Possible Drug-Induced Immune Thrombocytopenic Purpura includes some strategies for identifying drugs implicated in D-ITP.

Demonstration of drug-dependent binding of IgG to platelets in vitro can be important for diagnosis (see Fig. 134-7, *B*). Labeled immunoglobulin-specific probes (e.g., phase II assays) or GP capture techniques (phase III assays) can be used (see Table 134-3). In other cases, D-ITP test results are negative, but the diagnosis still seems likely based on clinical features and supporting literature (Fig. 134-8).

There are certain caveats in diagnostic testing. First, metabolites must sometimes be used to detect the IgG instead of the parent drug. Second, the target drug (or metabolite) must be included in the wash buffer used in these assays. Third, despite these maneuvers, the sensitivity of in vitro assays is relatively low, and the diagnosis of drug-induced immune thrombocytopenia often must be made on clinical grounds. Sometimes the diagnosis is confirmed by inadvertent or deliberate reexposure to the suspected drug. However, deliberate drug challenge is not often performed because of its potential risk.

Search Strategies When Investigating a Patient With Possible Drug-Induced Immune Thrombocytopenic Purpura

Four sources of information as to whether a drug has been implicated as a cause of D-ITP:

- **PubMed search** (http://www.ncbi.nlm.nih.gov/pubmed): [name of drug] and [thrombocytopenia]. By way of example, the author encountered a patient who developed severe thrombocytopenia 5 days after starting treatment with mirtazapine (see Fig. 134-8). Searching [mirtazapine] and [thrombocytopenia] identified one report[12] of mirtazapine-induced D-ITP syndrome.
- **Drug-induced thrombocytopenia website** (http://www.ouhsc.edu/platelets/ditp.html): Investigators at the University of Oklahoma published a comprehensive survey of drugs implicated in D-ITP using clinical criteria[13]; a website maintained by these investigators is updated every 2 years.
- **Database from drug-dependent platelet-reactive antibody testing** at the BloodCenter of Wisconsin, 1995-2010 (http://www.ouhsc.edu/platelets/InternetPostingLab2_18_11Frames.htm): the BloodCenter of Wisconsin maintains a website reporting its experience in detecting drug-dependent platelet-reactive antibodies.[14]
- **Combined approach that uses clinical criteria,[13] laboratory criteria,[14] and Adverse Event Reporting System.[8]** Figure 134-5 lists two dozen drugs for which convincing clinical and laboratory evidence exists.[8,9] To review the comprehensive list of all drugs investigated in this study,[8] interested readers can consult the online supplemental table (http.bloodjournal.hematologylibrary.org/content/suppl/2010/06/08/blood-2010-03-276691.DC1/TableS1.pdf).

A novel approach to identify drug-dependent platelet-reactive antibodies was reported by investigators at the Milwaukee Blood Center.[15] They used nonobese diabetic/severe combined immunodeficient (NOD/SCID) mice (which lack xenoantibodies, thereby allowing infused human platelets to circulate) to identify drug-dependent antibodies in patient sera, including antibodies that only recognize drug metabolites (presumably, mice produce the same or similar drug metabolites as humans, which are recognized by the drug-dependent antibodies).

Management

As many drugs as possible should be discontinued in patients with suspected drug-induced immune thrombocytopenia. If further drug treatment is necessary, an alternate, immunologically non–cross-reactive substitute should be used. Spontaneous improvement in the platelet count usually begins within a few days of discontinuing the offending drug, although in some cases, complete recovery may take 2 weeks or longer. Platelet transfusions should be given to patients with life-threatening bleeding. High-dose intravenous immunoglobulin (IVIG), 1 g/kg given over 6 to 8 hours, with a second dose 1 or 2 days later if required, may be helpful in some situations. Corticosteroids appear to be relatively ineffective for treatment of drug-induced immune thrombocytopenia.

GOLD-INDUCED THROMBOCYTOPENIA

Gold-induced immune thrombocytopenia occurs in as many as 1% to 3% of treated patients. A genetic predisposition is suggested by the association with HLA-DR3, which is found in approximately 85% of affected patients. The thrombocytopenia typically occurs during the first 20 weeks of therapy before a total of 1000 mg of gold has been given. Rarely, the thrombocytopenia begins much later, sometimes several months after discontinuation of the gold. Although the onset of thrombocytopenia typically is abrupt, regular platelet count monitoring is important because an early diagnosis can be made in some patients. The thrombocytopenia often persists for several months after discontinuation of the gold, probably because of gold-induced autoimmune thrombocytopenia (drug-independent gold-induced autoantibodies against GPV have been implicated) (see Fig. 134-4). Although most patients will eventually respond to corticosteroids, immediate, albeit often transient, correction of severe thrombocytopenia can usually be achieved with high-dose IVIG. Some patients with persisting thrombocytopenia benefit from splenectomy or use of gold-chelating agents (dimercaprol, *N*-acetylcysteine). The disorder is rarely encountered because the use of gold to treat rheumatic disorders has declined.

DRUG-INDUCED AUTOIMMUNE THROMBOCYTOPENIA

Certain drugs other than gold have been reported to initiate autoimmune thrombocytopenia (e.g., levodopa, procainamide).[4] Because the pathogenic antibodies are by definition drug independent, however, it is difficult to establish causation. The mumps–measles–rubella (MMR) vaccine can rarely (≈one in 40,000) cause a severe but generally self-limited thrombocytopenia that is clinically and serologically indistinguishable from childhood acute ITP; MMR vaccination of unimmunized children with ITP and revaccination of children with prior ITP does not lead to recurrent thrombocytopenia.[16]

DRUG-INDUCED IMMUNE THROMBOCYTOPENIA OF RAPID ONSET

A rapid onset of thrombocytopenia (within hours) can occur if a patient with preexisting drug-dependent antibodies is (re)exposed to the drug. This situation is relatively common in HIT (≈25% of

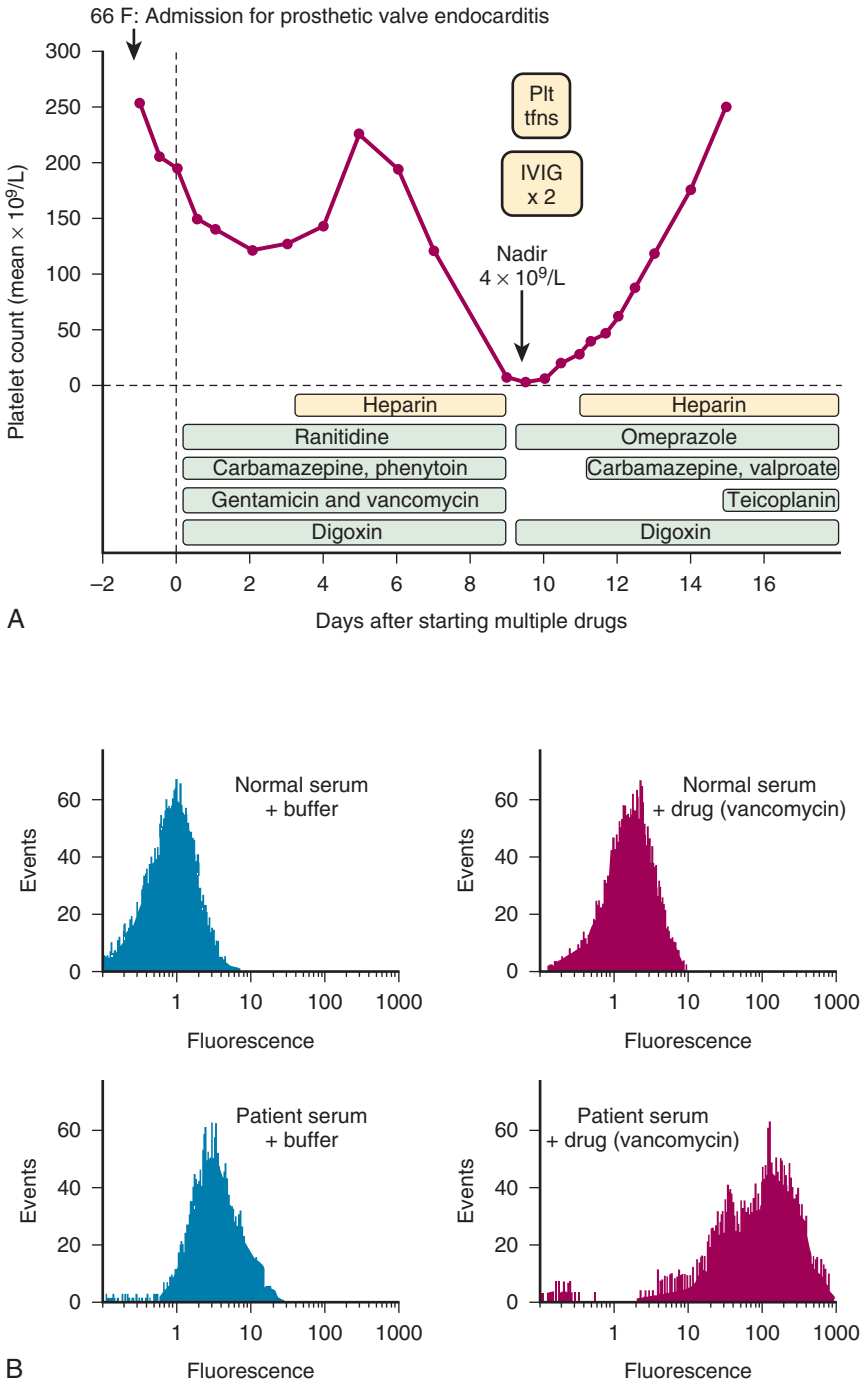

Figure 134-7 DRUG-INDUCED IMMUNE THROMBOCYTOPENIA (D-ITP) SECONDARY TO VANCOMYCIN. **A,** Timeline of D-ITP**.** A 66-year-old woman was admitted for prosthetic valve endocarditis 5 months after undergoing mitral valve replacement. The initiation of multiple new drugs and the onset 6 days later of progressively severe thrombocytopenia (platelet count nadir, 4×10^9/L on day 9) suggested D-ITP syndrome. However, the timing fit several drugs (ranitidine, carbamazepine, phenytoin, gentamicin, vancomycin, and digoxin). **B,** Drug-dependent binding of antibodies was demonstrated using patient serum and vancomycin. Also, test results for heparin-induced thrombocytopenia antibodies was negative. Thus the diagnosis of vancomycin-induced D-ITP syndrome was made based on clinical and serological grounds. The patient received treatment with high-dose intravenous immunoglobulin (IVIG) and platelet transfusions. *Plt tfns,* Platelet transfusions.

patients identified)[17] because repeated treatment with heparin is common and heparin use itself can result in the complication (HIT-associated thrombosis) that might lead to further use of heparin. Because HIT antibodies are transient, however, rapid-onset HIT occurs in patients with recent heparin exposures, usually within the past 100 days.[17] By contrast, repeated episodes of quinine-induced thrombocytopenia of abrupt onset can occur many months or even years apart because these antibodies persist for much longer. Thrombocytopenia of rapid onset is commonly seen with GPIIb/IIIa receptor antagonists (see next section).

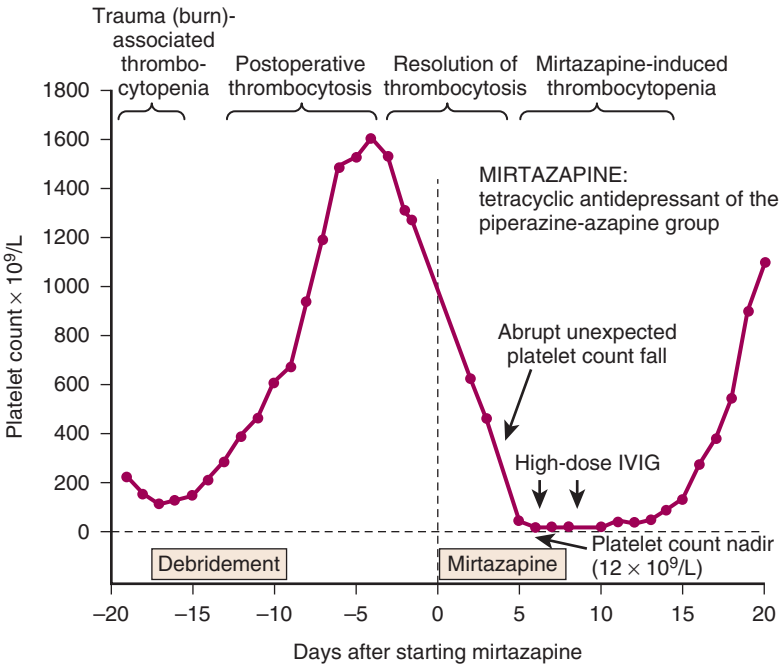

Figure 134-8 DRUG-INDUCED IMMUNE THROMBOCYTOPENIA (D-ITP) SECONDARY TO MIRTAZAPINE. The onset of severe thrombocytopenia (platelet count nadir, 12 × 10^9/L) on day 6 of mirtazapine therapy implicated this tetracyclic antidepressant of the piperazine-azapine group as a cause of D-ITP syndrome. The very rapid platelet count fall (which was already manifest on day 5 of mirtazapine therapy) is explained by reduced platelet production (because the patient's platelet count was declining from postoperative thrombocytosis). Although in vitro testing for mirtazapine-dependent antibodies was negative, the low sensitivity of these assays does not rule out mirtazapine as the cause of D-ITP syndrome, particularly in a high pretest probability scenario such as this.

THROMBOCYTOPENIA CAUSED BY GLYCOPROTEIN IIB/IIIA RECEPTOR ANTAGONISTS

Several thrombocytopenic syndromes have been reported with use of GPIIb/IIIa receptor antagonists (abciximab, eptifibatide, tirofiban) administered during percutaneous coronary interventions (e.g., angioplasty, stenting): (1) rapid-onset, severe thrombocytopenia within 12 hours of drug administration (in 0.4%-2% of patients), (2) rapid-onset pseudothrombocytopenia (in ~1% of patients exposed to abciximab [ReoPro]), (3) rapid-onset thrombocytopenia within 12 hours of a second exposure to a GPIIb/IIIa antagonist, and (4) delayed-onset thrombocytopenia beginning 5 to 7 days after drug administration (rare).[18] The frequency of rapid-onset thrombocytopenia is higher among patients who receive a second course of therapy, especially if it follows the initial exposure by only a few weeks. Thrombocytopenia typically is severe (median platelet count nadir, ~5 × 10^9/L to 10 × 10^9/L), but clinical effects vary dramatically, ranging from absence of petechiae or other signs of bleeding (in 50% of patients) to fatal hemorrhage (in <5%). Some patients develop anaphylactoid reactions accompanying the abrupt platelet count declines. Some investigators have proposed that the antibodies may cause thrombosis in some patients, likely because the pathogenic antibodies also activate platelets.[19]

These syndromes are caused by at least three mechanisms. First, antibodies of IgG (and possibly IgM) class can bind to neoepitopes on the GPIIb/IIIa complex generated by these drugs (or their metabolites)—that is, ligand-induced binding sites (see Fig. 134-4). Up to 5% of humans and nonhuman primates have naturally occurring IgG antibodies that will bind to GPIIb/IIIa receptors in the presence of drug, which could explain why rapid-onset thrombocytopenia occurs so frequently with these agents. A second mechanism is applicable to abciximab, a chimeric Fab fragment comprised of murine GPIIb/IIIa-reactive sequences and human framework sequences. Interestingly, although a high frequency of normal persons (74%) have antibodies that recognize platelets coated with abciximab, these "normal" antibodies were shown to differ from those detected in patients in whom thrombocytopenia developed after a second exposure to abciximab: whereas the pathogenic antibodies recognized murine sequences within abciximab, the "normal" (nonpathogenic) antibodies were specific for the carboxyl terminus (papain cleavage site) of Fab fragments prepared from normal human IgG. Drug-dependent antibodies also can be generated about 1 week after exposure. The antibodies differ among patients with respect to the precise neoepitopes recognized and display variable degrees of cross-reactivity among the different GPIIb/IIIa receptor antagonists ("fibans"); this explains why a repeat treatment course with another GPIIb/IIIa receptor antagonist may not necessarily cause thrombocytopenia. A third mechanism involves eptifibatide-dependent antibodies that activate platelets via their FcγIIa receptors.[19]

Some naturally occurring antibodies only bind to GPIIb/IIIa when the calcium concentration is low, thus explaining pseudothrombocytopenia—falsely low platelet count estimates caused by ex vivo aggregation of platelets in blood samples collected into calcium-chelating anticoagulants, especially EDTA. The rare syndrome of delayed-onset thrombocytopenia after brief exposure might result from high-titer GPIIb/IIIa-reactive antibodies that bind even in the absence of the drug.

Platelet transfusions are indicated in patients who are bleeding, although their efficacy has not been established. Platelet transfusions are most likely to be effective for the treatment of abciximab-induced thrombocytopenia because the drug binds so tightly to GPIIb/IIIa that little abciximab is free to bind to the transfused platelets. Platelet transfusions are not indicated in pseudothrombocytopenia, which underscores the importance of reviewing the blood film when a low platelet count is reported after treatment with one of these agents.

Various in vitro assays using flow cytometry or enzyme-linked immunosorbent assay (ELISA) have been developed to detect these antibodies. Because some pathogenic antibodies are naturally occurring, it is theoretically possible to identify patients at high risk for rapid-onset thrombocytopenia in elective situations (see box on Approach to Patients With Thrombocytopenia Following Percutaneous Coronary Interventions).

MISCELLANEOUS DRUG-INDUCED THROMBOCYTOPENIC SYNDROMES

Drug-Induced Thrombotic Microangiopathy

Several drugs can trigger a syndrome of thrombocytopenia, fragmentation hemolysis, and renal failure known as *drug-induced thrombotic microangiopathy*. This syndrome has been established for quinine, in which multiple quinine-dependent antibodies reactive against platelets, RBCs, leukocytes, and endothelial cells have been reported.

Approach to Patients With Thrombocytopenia Following Percutaneous Coronary Interventions

Four diagnoses should be considered in patients who develop thrombocytopenia within minutes or a few hours after a percutaneous coronary intervention (PCI) and have received one or more of the following agents: (1) platelet GPIIb/IIIa inhibitor (e.g., abciximab, eptifibatide, tirofiban), (2) heparin, or (3) iodinated contrast agent.

- **GPIIb/IIIa inhibitor–induced pseudothrombocytopenia.** The patient has no symptoms or signs of bleeding, and platelet aggregates are seen in the blood film. The platelet count is falsely reported as low by the automated particle counter, which fails to count aggregated platelets. No treatment is required.
- **GPIIb/IIIa inhibitor–induced thrombocytopenia.** The platelet count falls abruptly, often to profoundly reduced levels (typical nadir, $<20 \times 10^9$/L). Hemostatic impairment is variable, ranging from no petechiae to fatal hemorrhages; occasionally, patients develop anaphylactoid reactions or even associated thrombosis. Treatment involves stopping all platelet antagonists and anticoagulants and giving platelets if the patient has signs of bleeding. Prophylactic platelet transfusions also can be considered if the platelet count is very low (e.g., $<10 \times 10^9$/L). Testing for drug-dependent antibodies can be accomplished using flow cytometry or ELISA.
- **Rapid-onset HIT.** In patients who have preexisting HIT antibodies because of recent heparin exposure (generally within the past 100 days), rapid-onset HIT can occur when heparin is given during PCI. This is much less common than GPIIb/IIIa inhibitor–induced thrombocytopenia or pseudothrombocytopenia, so presumptive treatment of HIT with a nonheparin anticoagulant is rarely indicated in this situation. The platelet count nadir is usually much higher than with GPIIb/IIIa inhibitor–induced thrombocytopenia.
- **Radiocontrast-induced ITP.** Very rarely, patients who have previously received iodinated contrast can develop abrupt-onset, severe thrombocytopenia after exposure to contrast during PCI. Platelet transfusions (with or without high-dose IVIG) are appropriate for a bleeding patient.

Immune mechanisms could also be present when TTP-like illnesses are associated with drugs such as ticlopidine, clopidogrel, and simvastatin; for example, autoantibodies against vWF-cleaving metalloproteinase have been identified in ticlopidine-induced TTP. Treatment is with plasmapheresis, as for more typical TTP. Typically, affected patients recover, although some require short-term hemodialysis.

Although a similar syndrome may be caused by mitomycin, gemcitabine, cyclosporine, and tacrolimus, it should be noted that many patients who receive these drugs have an underlying illness (e.g., gastric adenocarcinoma, BM transplantation, collagen vascular disease) that itself can be complicated by thrombotic microangiopathy; moreover, high cumulative doses of the implicated drug have usually been received, suggesting a distinct, perhaps nonimmune pathogenesis. Furthermore, these patients tend to be less responsive to plasma exchange than those with idiopathic TTP.

Drug-Induced Disseminated Intravascular Coagulation

On rare occasions, quinine causes severe thrombocytopenia accompanied by marked coagulation abnormalities indicative of DIC. This syndrome overlaps that of quinine-induced thrombotic microangiopathy, and the explanation for the prominent coagulopathy is unknown. Although all patients with HIT have biochemical evidence of increased thrombin generation, only about 10% to 20% have overt DIC; however, these patients often present with large and small vessel thrombosis.

Nonidiosyncratic Drug-Induced Thrombocytopenia

Most antineoplastic drugs produce dose-dependent pancytopenia because of their effect on hematopoietic cells, including megakaryocytes and their progenitor cells. Typically, the platelet count nadir occurs at a predictable time after treatment, and the count then quickly recovers. Unexpectedly severe or prolonged thrombocytopenia in patients receiving chemotherapy should suggest alternate explanations (e.g., idiosyncratic thrombocytopenia caused by another drug).

Mild to moderate thrombocytopenia develops in approximately 20% of patients who take valproic acid (an antiepileptic agent); bleeding symptoms are uncommon. The mechanism of thrombocytopenia in this setting is unknown, but the condition appears to be nonidiosyncratic because the risk of thrombocytopenia correlates strongly with serum concentrations of valproic acid metabolite.[20] Amrinone is another agent that can cause mild, dose-dependent thrombocytopenia.

Rapid Nonimmune Drug-Induced Thrombocytopenia

Some drugs produce rapid but generally mild and transient drops in the platelet count. These drugs include heparin, protamine, bleomycin, hematin, desmopressin (particularly in patients with type 2B von Willebrand disease), and porcine factor VIII. The mechanisms for thrombocytopenia in these syndromes are obscure.

Drug Hypersensitivity Reactions

Mild to moderate thrombocytopenia is sometimes observed in patients with systemic drug hypersensitivity reactions. Comorbid clinical features can include generalized rash, fever, cholestasis, and leukopenia. Allopurinol, isoniazid, sulfasalazine, and phenothiazine drugs, among others, have been implicated in these reactions.

Thrombocytopenia Secondary to Biologic Response Modifiers

Use of purified or recombinant biologic response modifiers such as interferon, interleukin-2, and certain colony-stimulating factors has resulted in severe, reversible thrombocytopenia in some patients. Antilymphocyte globulins also can produce severe thrombocytopenia.

OTHER CAUSES OF DESTRUCTIVE THROMBOCYTOPENIA

Incidental Thrombocytopenia of Pregnancy

Maternal thrombocytopenia occurs in 4% to 8% of pregnancies.[21] Most affected women are healthy and have no history of thrombocytopenia, and their thrombocytopenia is incidentally detected by routine blood testing. The cause of the mild reduction in platelet count ($\sim 75 \times 10^9$/L to 150×10^9/L) is believed to represent a leftward shift in the normal platelet count range during pregnancy related to one or more of hemodilution, reduced platelet production, or increased platelet turnover.[21] This condition is benign and is not associated with an increased risk for maternal bleeding or neonatal thrombocytopenia. Accordingly, no special maneuvers are indicated in these women, and the route of delivery should be determined by obstetric indications. Epidural anesthesia is believed to be safe if the platelet count is at least 75×10^9/L.

Preeclampsia and Eclampsia

Preeclampsia is characterized by the onset of hypertension and proteinuria during pregnancy, especially in a primigravida near term. Preeclampsia complicates approximately 5% of pregnancies, and the frequency is higher in black women. Thrombocytopenia occurs in up to 50% of preeclamptic patients, and its severity generally parallels that of the underlying preeclampsia.[21] A subset of patients with preeclampsia has microangiopathic hemolysis, elevated liver enzymes, and low platelets, widely known as the HELLP syndrome. This condition usually indicates severe preeclampsia and is associated with a higher risk of fetal and maternal complications, including maternal hepatic rupture. Repeated clinical and laboratory assessment of these patients is important because this syndrome can mimic other life-threatening complications of pregnancy, such as overt DIC, TTP, septicemia, and acute fatty liver of pregnancy.

Increased platelet destruction is the mechanism for the thrombocytopenia in preeclampsia. However, activation of the coagulation system is relatively modest, suggesting that thrombin generation may not be a major driver of the thrombocytopenia. Endothelial dysfunction (e.g., impaired nitric oxide synthesis) is a potential explanation for increased platelet turnover in preeclampsia.

Pharmacologic control of hypertension and rapid delivery are the treatments for preeclampsia and usually result in resolution of the thrombocytopenia within a few days. If delivery is not an option, treatment with bed rest and aggressive antihypertensive therapy has been reported to result in an improved platelet count. However, the clinical course is markedly variable, and some patients develop life-threatening organ failure. Plasmapheresis has been used in some patients, especially if there is evidence of thrombotic microangiopathy and organ dysfunction. Plasma exchange would seem appropriate for patients whose clinical picture has features that overlap with those of TTP.

Infection

Infection is a common cause of thrombocytopenia, occurring in approximately 50% to 75% of patients with bacteremia or fungemia and in almost all patients with septic shock or DIC. Even when caused by bacteremia, the thrombocytopenia generally is mild to moderate in severity and usually is not accompanied by significant coagulation abnormalities or bleeding. The likelihood of laboratory evidence for DIC increases as the platelet count falls below 50 × 109/L. The mechanisms for thrombocytopenia in septicemia in the absence of DIC are uncertain but could include chemokine-induced macrophage ingestion of platelets (hemophagocytosis[22]) and direct activation of platelets by endogenous mediators of inflammation (e.g., platelet-activating factor) or certain microbial products. In rare situations, platelet-reactive autoantibodies are implicated. Various explanations for thrombocytopenia in different types of infection are listed in Table 134-5.

Unexplained thrombocytopenia in a hospitalized patient warrants studies to exclude infection, such as blood cultures. Prompt recognition and treatment of the infection constitute the most important therapy because platelet count recovery tends to parallel the resolution of the infection. Prophylactic platelet transfusions are generally not required unless the platelet count falls below 10×10^9/L or comorbid clinical features increase the likelihood of serious bleeding (e.g., concomitant coagulopathy, an invasive procedure, uremic platelet dysfunction). The use of heparin for patients with septic shock and DIC is controversial. However, heparin may be of benefit in patients with clinical evidence of DIC and microvascular thrombosis (e.g., acral tissue ischemia or necrosis). The possibility of acquired protein C deficiency complicating acute DIC also should be considered in septic patients with purpura fulminans, such as that secondary to meningococcemia, in whom treatment with vitamin K, plasma, and possibly recombinant activated protein C could be beneficial.

Thrombocytopenia in patients infected with HIV poses a special diagnostic problem because there are many potential explanations for the thrombocytopenia (see Chapter 159). These include immune platelet destruction, impaired platelet production secondary to HIV infection of megakaryocytes, drug-induced myelosuppression (commonly implicated drugs include zidovudine, ganciclovir, and trimethoprim-sulfamethoxazole), HIV-associated thrombotic microangiopathy, hypersplenism, and BM infiltration by tumor or opportunistic infections. Platelet kinetic studies have shown a complex interaction of decreased platelet production, increased platelet destruction, and splenic platelet sequestration. Immune mechanisms for platelet destruction include antibodies that cross-react with GPIIb/IIIa complexes ("molecular mimicry") and immune complexes containing IgM antiidiotype antibodies (which could explain the paradox of high levels of platelet-associated IgG and IgM with low serum levels of platelet-reactive antibodies). Anti-HIV therapy (e.g., zidovudine, HAART) often raises the platelet count in patients with HIV-associated thrombocytopenia. Most patients with HIV-associated thrombocytopenia respond to conventional treatments for ITP, including corticosteroids; splenectomy; IVIG; and, particularly, anti-D.

Table 134-5 Mechanisms for Thrombocytopenia Complicating Infections

Mechanism for Thrombocytopenia	Selected Example(s)*
Increased Platelet Destruction	
DIC	Meningococcemia
Hemophagocytosis	Septicemia, EBV infection
Platelet-reactive autoantibodies (acute)	Varicella, subacute bacterial endocarditis (rare)
Platelet-reactive autoantibodies (chronic)	HIV infection
HUS	Verocytotoxin-producing *Escherichia coli, Shigella* spp., HIV infection
Antibodies against platelet-adsorbed microbial antigens	Malaria
Hypersplenism	
Acute	Disseminated *Mycobacterium avium* infection in HIV infection
Chronic	Viral chronic active hepatitis, malaria
Decreased Platelet Production	
Replacement of BM by granulomas	Ehrlichiosis, tuberculosis
Infection of megakaryocytes	HIV infection
Transient virus-induced aplasia	Parvovirus B19 infection (erythroblastopenia predominates)
Multiple Mechanisms	
Platelet destruction plus hypersplenism	Recurrent malaria
Increased platelet destruction, decreased platelet production, hypersplenism	Chronic HIV infection

Systemic Lupus Erythematosus

Immune-mediated thrombocytopenia, which occurs in as many as 25% of patients with SLE, is associated with a twofold increased risk

of organ damage events. Many different types of platelet–IgG interactions are described (e.g., antiglycoprotein, antiglycolipid, β_2-glycoprotein I (β_2GPI)–containing immune complexes). In addition, antithrombopoietin, anti–c-Mpl (thrombopoietin receptor), and anti-CD40 ligand autoantibodies have been reported. Multiple causes for thrombocytopenia—increased platelet destruction, hypersplenism, and even impaired platelet production related to antibody-induced megakaryocytic hypoplasia—have been reported. The predominant explanation for thrombocytopenia in SLE remains unknown.

Several thrombocytopenic syndromes are seen in patients with SLE. For many patients, the thrombocytopenia is chronic, resembling ITP, and is the predominant clinical manifestation of the lupus. Often, these patients have a prolonged bleeding time despite mild thrombocytopenia. Some thrombocytopenic patients with SLE have antiphospholipid (aPL) antibodies and are at increased risk for thrombotic rather than bleeding complications (see Chapter 143). Acute, severe thrombocytopenia can be a prominent feature in patients with a severe multisystem exacerbation of lupus. Rarely, patients with SLE develop an illness that closely resembles TTP or HUS; these patients should be treated with plasma exchange. Thrombocytopenia as a feature of SLE-associated, viral-induced macrophage activation syndrome has been reported.

Treatment of the thrombocytopenia of SLE is similar to that of ITP (see Chapter 143). Corticosteroids constitute the first line of therapy, but many patients do not respond or require high doses. High-dose IVIG may be useful in patients who are bleeding to transiently increase the platelet count. Before resorting to splenectomy, one could try danazol (an attenuated androgen) in doses of 200 to 800 mg/day. Higher doses can cause hepatitis. Typically, several weeks are required before a benefit is seen. Splenectomy probably is as effective in achieving platelet count remission in SLE as in ITP. Patients with refractory thrombocytopenia sometimes benefit from more aggressive therapies, such as azathioprine, intermittent-pulse cyclophosphamide, plasmapheresis synchronized with pulse cyclophosphamide, cyclosporine, thrombopoietin mimetics, or rituximab.

Antiphospholipid Syndrome

Antiphospholipid syndrome (APS; see Chapter 143) is characterized by occurrence of one or more clinical events (e.g., venous, arterial or small vessel thrombosis, pregnancy loss, preterm delivery for patients with severe preeclampsia or placental insufficiency) associated with IgG, IgM, or IgA antibodies that recognize a complex of one or more protein cofactors (e.g., β_2GPI, annexin V, prothrombin, protein C, protein S) bound to negatively charged phospholipid.[23] Many patients (30%-50%) with this syndrome have thrombocytopenia, which is typically mild and intermittent; approximately 15% have autoimmune hemolysis. The APS should be considered in patients who develop idiopathic lower limb or abdominal vein (mesenteric, renal, adrenal) thrombosis, cerebral venous (dural sinus) thrombosis, cardiac valvulitis, nonatheromatous arterial thrombosis (especially thrombotic stroke in a patient younger than 50 years of age), dermal microvascular thrombosis (acrocyanosis, digital ulceration or gangrene, livedo reticularis), or acute multiorgan failure associated with DIC or widespread thrombosis of the microvasculature (catastrophic APS).

The mechanism of the prothrombotic tendency in patients with APS remains elusive, but interference with endothelial cell function, impaired fibrinolysis, antibody-mediated platelet activation, formation of endothelial microparticles, interference with thrombin and factor Xa degradation by antithrombin, disturbance in the protein C anticoagulant pathway or anticoagulant activity of β_2GPI all have been described. Disruption of the antithrombotic annexin V antithrombotic "shield" by aPL antibodies has been proposed to explain pregnancy losses through placental vascular thrombosis. Evidence indicates that thrombocytopenia in patients with APS is associated with platelet GP-reactive autoantibodies.

Antiphospholipid antibodies are detected by either of two methods: (1) solid-phase ELISA with purified phospholipids (usually cardiolipin) as target antigens or (2) a "functional" assay for so-called lupus anticoagulant (LA) activity, shown by demonstrating inhibition of certain phospholipid-dependent coagulation assays, such as the aPTT or the Russell viper venom time. Although aPL antibodies frequently are detected in patients with SLE, they also can be found in patients with other autoimmune disorders, malignancy, or infections or as a complication of certain drugs (e.g., procainamide). Often no associated condition is identified ("primary" APS). aPL antibodies of low titer are sometimes found in normal persons, particularly elderly individuals, or during normal pregnancy. Autoantibody "cluster" studies show that anticardiolipin, LA, and anti–double-stranded DNA antibodies occur together more often than with other SLE-associated autoantibodies (e.g., anti-Sm, anti-Ro, anti-RNP).

There are intriguing parallels between the APS and HIT: in both disorders, the antibodies are directed at a protein target (β_2GPI and PF4, respectively) bound to a negatively charged species (anionic phospholipid and heparin, respectively). For both, high-titer IgG antibodies that result in a positive "functional" test result (LA activity and HIT-IgG–induced platelet activation, respectively) are most likely to be associated with clinical disease. Both disorders are characterized by the paradox of thrombocytopenia associated with increased risk for venous and arterial thrombosis.

To help physicians diagnose the APS, clinical and laboratory criteria have been developed. The laboratory criteria include the presence of anticardiolipin, anti-β_2GPI, or LA antibodies (moderate- to high-titer IgG or IgM) on two or more occasions at least 12 weeks apart. The major clinical criteria are thrombosis and complications of pregnancy. Thrombosis can involve large arteries or veins or small vessels within any organ. The complications of pregnancy include one or more unexplained deaths of normal fetus(es) after week 10 of gestation or premature births (before 34 weeks) or more than three spontaneous abortions before week 10 of gestation. Some experts advocate for thrombocytopenia to be included within the criteria for APS.[24]

Specific treatment for the thrombocytopenia is not usually required. For many patients, long-term anticoagulant or antiplatelet therapy, or both, are needed to prevent recurrent thrombosis. For patients with recurring pregnancy losses and aPL antibodies, randomized trials have documented the benefit of low-dose aspirin combined with either low-dose UFH or low-molecular-weight heparin (LMWH).

Malignancy

Thrombocytopenia complicating malignant disorders most frequently results from antineoplastic treatment or BM replacement by tumor. However, certain thrombocytopenic syndromes have been associated with malignancy, including autoimmune thrombocytopenia, DIC, and thrombotic microangiopathy.

Immune thrombocytopenia attributable to platelet GP-reactive autoantibodies can complicate neoplastic lymphoproliferative diseases such as Hodgkin disease, non-Hodgkin lymphoma, chronic lymphocytic leukemia, and multiple myeloma. Sometimes the thrombocytopenia responds to treatment of the neoplasm, although in some patients (particularly those with Hodgkin disease), the thrombocytopenia is indistinguishable from ITP and is not related to the activity of the lymphoma.

Disseminated intravascular coagulation occurs in certain malignancies, particularly adenocarcinomas of the pancreas, stomach, lung, colon, breast, and prostate. Some patients present with venous or, less commonly, arterial thrombosis as the first clinical manifestation of their malignancy. In these patients, the presence of thrombocytopenia is an important clue that should prompt investigations for DIC, such as measurement of fibrinogen or D-dimer levels. In the author's experience, the platelet count typically rises to normal or even elevated levels with heparin therapy because heparin ameliorates the DIC process; however, recurrent thrombocytopenia and thrombosis can occur within hours of discontinuing the heparin therapy. Cancer patients with DIC and venous thrombosis also are at increased risk

for warfarin-associated venous limb gangrene. The role of various tumor-associated procoagulant substances—such as "cancer procoagulant" (a 68-kd cysteine proteinase that activates factor X independently of tissue factor/factor VIIa) and cancer-associated tissue factor (which is expressed on tumor cells, as well as circulating microparticles[25])—suggest pathophysiologic parallels with microthrombosis in HIT because both cancer-associated DIC and acute HIT are risk factors for phlegmasia cerulean dolens and venous limb gangrene during anticoagulation with warfarin. Thus cancer patients with DIC should receive heparin (especially LMWH) rather than warfarin anticoagulation (see box on Diagnostic Considerations in the Patient With Limb Ischemia and Thrombocytopenia in Chapter 135). DIC with hemorrhagic manifestations is characteristically seen in some patients with prostate cancer and in many patients with acute promyelocytic leukemia. It is crucial to recognize promyelocytic leukemia because treatment with all-*trans*-retinoic acid produces differentiation of the malignant cells, thereby rapidly reducing the life-threatening bleeding risks attributable to hyperfibrinolysis.

A destructive thrombocytopenic disorder that resembles HUS or TTP has been described in patients with advanced cancer. In some patients, mitomycin, gemcitabine, or other drugs may have contributed to the microangiopathy. DIC usually is not present. Some patients respond transiently to plasmapheresis, but for many, response to any therapy is poor.

Macrophage Activation (Hemophagocytic) Syndrome

The macrophage activation (or hemophagocytic) syndrome comprises a heterogeneous group of disorders characterized by variable cytopenias and morphologic evidence of macrophage phagocytosis of RBCs, granulocytes, and platelets; hyperferritinemia, hypercytokinemia, and sepsis-like features are characteristic, with potential for evolution to fatal multiple organ failure.[26] Some adult patients have an aggressive disease characterized by high fever, weight loss, prominent hepatosplenomegaly, severe pancytopenia, elevated liver enzymes, and often a terminal infection. Both T- and B-cell lymphomas can explain such a dramatic syndrome. However, similar patients with fulminant illness have been described after otherwise unremarkable bacterial or viral infections (particularly those caused by Epstein-Barr virus). In children, the high mortality rate associated with hemophagocytic lymphohistiocytosis warrants aggressive treatment, including antineoplastic chemotherapy and BM transplantation. Nonneoplastic but nonetheless severe hemophagocytosis can be seen in patients with certain infections (e.g., babesiosis, ehrlichiosis, HIV infection), as well as in patients with rheumatologic disorders (SLE, Still disease, ankylosing spondylitis). Laboratory indicators of macrophage activation syndrome include markedly elevated ferritin,[27] high levels of soluble CD163 and CD25, and morphologic evidence of hemophagocytosis. Treatment should be directed at the underlying illness. Early administration of corticosteroids and high-dose γ-globulin (IVIG) appears to benefit some patients with nonneoplastic macrophage activation syndrome.

Solid Organ and Bone Marrow Transplantation

Thrombocytopenia commonly occurs during episodes of solid organ allograft rejection. It is possible that platelet activation and deposition in the transplanted organ vasculature contribute to the rejection process. Antirejection therapies can also cause thrombocytopenia through increased platelet destruction (antilymphocyte globulin) or BM suppression (azathioprine). Posttransplantation HUS develops in approximately 5% of renal transplant recipients and in even fewer recipients of liver or heart transplants. Although cyclosporine sometimes is implicated in HUS, it usually can be safely resumed after recovery.

Early, severe thrombocytopenia caused by BM-ablative therapy invariably accompanies BM transplantation (BMT). Platelet count recovery to greater than 50×10^9/L is more rapid (16 vs. 35 days) in patients receiving autologous mobilized peripheral blood progenitor cells than in those undergoing autologous BMT. Severe persistent thrombocytopenia despite recovery of RBCs and WBCs is relatively common after BMT or peripheral blood transplantation; autoimmune thrombocytopenia has been implicated in some patients. Late-onset thrombocytopenia after BMT that responds to corticosteroids, IVIG, and splenectomy also has been attributed to autoimmune thrombocytopenia. Rarely, transplantation-associated alloimmune thrombocytopenia can be caused by donor–recipient incompatibility involving platelet-specific alloantigens such as Pl^{A1} (HPA-1a) or Br^a (HPA-5b).

A syndrome of thrombocytopenia, RBC fragmentation, and renal impairment can occur in as many as 10% of patients undergoing BMT, usually beginning 3 to 12 months after transplantation (BMT-associated thrombotic microangiopathy). The pathogenesis remains obscure; reduced ADAMTS13 levels have not been implicated. The hematologic abnormalities can be mild and remit spontaneously, although patients often have residual azotemia and hypertension. More severely affected patients usually do not benefit from plasmapheresis. The syndrome has a poor overall prognosis, and many patients die irrespective of any intervention.

Cardiopulmonary Bypass Surgery

Excess bleeding is a common problem in patients who undergo heart surgery using cardiopulmonary bypass. Many of these patients receive blood transfusions, and approximately 5% require reoperation for postoperative bleeding.

Thrombocytopenia and transient platelet dysfunction (see Chapter 161) are observed in virtually every patient. Typically, the platelet count falls by 35% to 65%, primarily as a result of hemodilution but also because of bleeding and losses within the extracorporeal perfusion device. Because patients invariably receive heparin during cardiac surgery and have often received heparin in the remote or recent past, immune HIT is frequently considered in the differential diagnosis of early-onset and persisting postcardiac surgery thrombocytopenia; however, HIT is an unlikely explanation for thrombocytopenia even when anti-PF4/heparin antibodies are positive.[28]

The bleeding time rises markedly during heart surgery (to greater than 30 minutes) but usually improves to less than 15 minutes shortly after surgery and to normal several hours later. By contrast, the thrombocytopenia persists for 3 to 4 days followed by recovery of the platelet count to values exceeding the preoperative baseline.

The pathogenesis and clinical significance of the hemostatic defect in these patients remain uncertain, but the explanation probably is multifactorial. Studies have described transient, *intrinsic* defects in platelet function. These defects include decreased in vitro platelet aggregation, decreased platelet surface membrane proteins, selective depletion of platelet α-granules, and evidence of in vivo platelet activation and platelet vesiculation. The platelet dysfunction in heart surgery also is attributable to an *extrinsic* platelet defect resulting from thrombin inhibition by the high doses of heparin. Furthermore, an important role for hyperfibrinolysis in the pathogenesis of bleeding is shown by elevated D-dimer levels in bleeding patients, as well as the efficacy of antifibrinolytic agents in the prevention and treatment of heart surgery–associated bleeding. Other factors in some patients include residual heparin effect after bypass (including heparin rebound) and preoperative use of aspirin. Treatment of platelet dysfunction after cardiopulmonary bypass is discussed in Chapter 161.

THROMBOCYTOPENIA ASSOCIATED WITH CARDIOVASCULAR DISEASE

Congenital Cyanotic Heart Disease

Thrombocytopenia caused by a decrease in platelet life span occurs in some patients with severe cyanotic congenital heart disease and is approximately related to the severity of the polycythemia. Bleeding

occurs in a few patients and can be related to platelet function defects, coagulopathy, or hyperfibrinolysis. Reducing the hematocrit by phlebotomy sometimes helps to correct the hemostatic defects.

Valvular Heart Disease

Increased platelet turnover is common in valvular heart disease, and some patients have mild thrombocytopenia. The pathogenesis of the platelet consumption is not well understood, but the defect could be related to increased platelet–vWF interactions at high shear. Indeed, high-molecular-weight multimers of vWF are reduced in some of these patients, which could explain why bleeding from gastrointestinal angiodysplasia in patients with aortic stenosis (Heyde syndrome) typically resolves after aortic valve replacement.[29] Thrombocytopenia secondary to consumptive coagulopathy can be seen in intracardiac thrombosis associated with valvular heart disease.

Pulmonary Vascular Disorders

Disorders characterized by pulmonary hypertension can be accompanied by thrombocytopenia, the pathogenesis of which is poorly defined. Thrombocytopenia can occur in association with pulmonary embolism,[30] possibly as a result of DIC. When evaluating such patients, the clinician should inquire about current or recent heparin exposure because HIT and pulmonary embolism are strongly associated.

HEMODILUTION AND PLATELET CONSUMPTION AFTER SURGERY

Platelet count declines of 30% to 70% occur universally after major surgery and reflect the combined effects of hemodilution and increased platelet consumption. Such hemodilution-associated thrombocytopenia is especially prominent after cardiac surgery and is proportional to the amount of fluids (crystalloid, colloid, blood products) administered. The platelet count fall is abrupt and is evident a few hours after surgery. Dilutional coagulopathy also occurs, which is responsible for the minor to moderate increases in coagulation test results that occur transiently after surgery.

Perioperative hemodilution is also usually accompanied by increased platelet consumption related to the effects of surgery. This helps to explain why the postsurgery platelet count usually continues to decline over the next 1 to 3 days, with the postoperative nadir (lowest platelet count value) usually occurring at a median of postoperative day 2, with a range between postoperative days 1 to 4 (Fig. 134-9).[2] Subsequently, there is a rise in the platelet count that peaks at approximately day 14 at levels often two to three times the patient's preoperative baseline before it returns to baseline over the next 2 weeks (≈day 28). As described earlier in this chapter (see Fig. 134-1), these platelet count changes reflect thrombopoietin physiology.

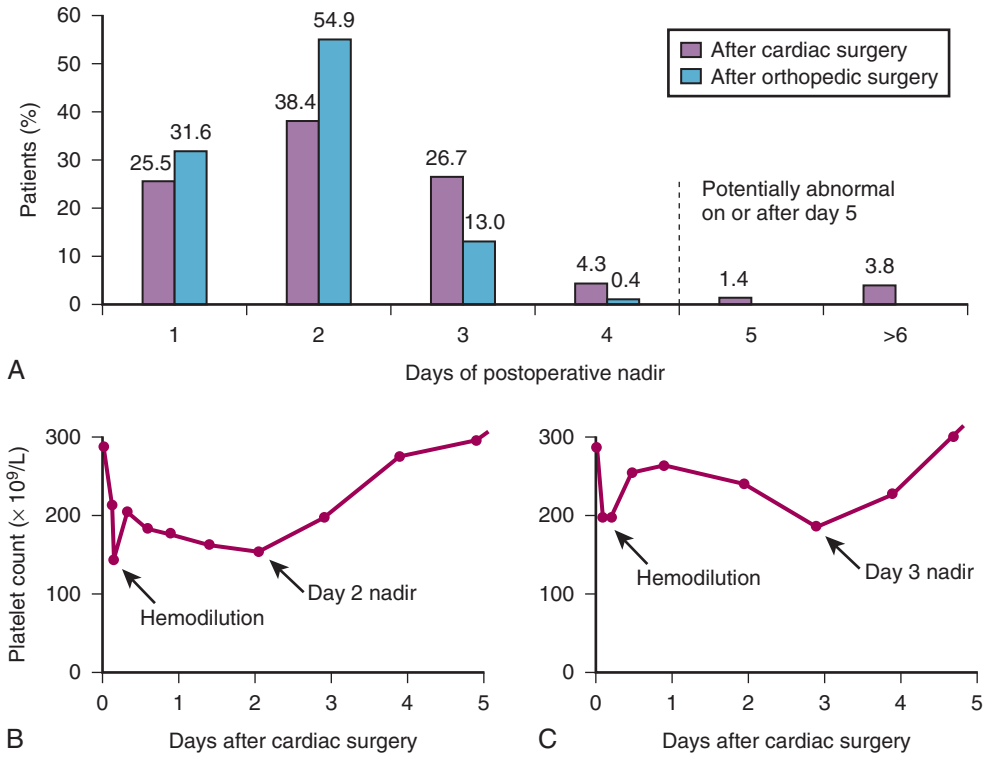

Figure 134-9 EARLY POSTOPERATIVE PLATELET COUNT DECLINES. **A,** Distribution of early postoperative count nadirs. For both orthopedic and cardiac surgery patients, day 2 represents the most common day for the postoperative platelet count nadir to occur (data exclude day 0); beyond postoperative day 4, it is likely that a superimposed thrombocytopenic disorder is occurring. **B** and **C,** Representative post–cardiac surgery platelet count declines. Both patients illustrate early hemodilution effects (day 0) and subsequent additional early platelet count declines with nadirs of day 2 **(B)** and day 3 **(C)**. Neither patient received platelet transfusions. *(From Greinacher A, Warkentin TE: Acquired non-immune thrombocytopenia. CHAPTER 135

HEPARIN-INDUCED THROMBOCYTOPENIA

Theodore E. Warkentin

Heparin-induced thrombocytopenia (HIT) is the most important drug-induced immune-mediated cytopenia for several reasons. First, heparin is a widely used anticoagulant (see Chapter 151). Second, HIT is relatively common, occurring in approximately 1% to 3% of postoperative patients and 0.2% to 0.5% of medical patients who receive unfractionated heparin (UFH) derived from porcine intestine for 7 to 14 days.[1] Third, HIT frequently causes life- and limb-threatening venous or arterial thrombosis. Finally, there are several pitfalls of HIT management, including the potential for thrombocytopenia and/or thrombosis to worsen despite stopping heparin, the high risk for warfarin-associated microthrombosis (most often manifesting as venous limb gangrene), and the potential for failure of approved direct thrombin inhibitor (DTI) therapy because of the confounding of activated partial thromboplastin time (aPTT)-monitored dosing that results from HIT-associated coagulopathies.

HIT is caused by platelet-activating immunoglobulin G (IgG) antibodies that bind to multimolecular complexes of platelet factor 4 (PF4) bound to heparin.[2,3] Although anti-PF4/heparin antibodies are frequently triggered by heparin therapy, relatively few patients develop clinically evident HIT. Indeed, a major current problem with HIT is its "overdiagnosis"[4]: only 5% to 10% of patients who are referred for antibody testing have a serologic profile that supports a diagnosis of HIT.[5] The challenge for the clinician is to discern which of the (many) patients who develop thrombocytopenia in association with heparin therapy really have HIT, a conundrum magnified by the observation that at most 50% of anti-PF4/heparin antibody–positive patients have "true" HIT, as indicated by the presence of platelet-activating IgG antibodies.[1,5]

EPIDEMIOLOGY

Table 135-1 lists risk factors for HIT. The highest risk for HIT is seen in patients with multiple interacting risk factors (e.g., females given postoperative thromboprophylaxis with UFH for 2 weeks [frequency approximately 5%]).[6] Even higher frequencies (approximately 10%) are reported in patients with ventricular assist devices who are receiving therapeutic doses of UFH. Ironically, even though the risk for HIT appears to be somewhat higher in women (odds ratio, 1.5 to 2.0),[6] HIT is rare in pregnancy, particularly with the use of low-molecular-weight heparin (LMWH). The synthetic antithrombin-binding sulfated pentasaccharide, fondaparinux, although similarly immunizing as LMWH, is much less likely than LMWH to cause HIT, likely because fondaparinux does not usually increase the platelet-activating potential of HIT antibodies.[7] Indeed, fondaparinux appears to be an effective treatment for HIT (discussed later).

Only a minority of patients who form anti-PF4/heparin antibodies following heparin treatment develop clinically evident HIT.[2,3] The proportion of antibody-positive patients who develop HIT ranges from as high as one-third (e.g., post–orthopedic surgery thromboprophylaxis with UFH) to as few as 1 in 50 (post–cardiac surgery patients).[1,2] Notably, the risk for HIT in post–cardiac surgery patients who receive UFH thromboprophylaxis is only approximately 1% even though as many as 50% to 80% of patients develop detectable anti-PF4/heparin antibodies within 2 weeks of surgery.[1] In general, those at highest risk for HIT are the subgroup of patients whose anti-PF4/heparin antibodies evince strong platelet-activating properties in vitro.[2,3] However, patient-dependent susceptibility factors are also important, because at most only half of all patients who form platelet-activating antibodies develop HIT.

PATHOBIOLOGY

Fig. 135-1 illustrates several features of HIT pathogenesis. Heparin binds reversibly and saturably to platelets and can weakly activate platelets in vitro through potentiation of $\alpha_{IIb}\beta_3$-mediated outside-in signaling.[8] In general, the direct platelet-activating effects of heparin, as well as its immunogenicity, are proportional to its molecular mass and degree of sulfation; consequently, LMWH is less likely to cause HIT than UFH.[1,2,6]

Platelet activation by HIT antibodies occurs because platelet-activating HIT-IgG cross-link platelet FcγIIa receptors.[1-3] The HIT antigens reside on large multimolecular complexes formed between cationic PF4—a member of the CXC subfamily of chemokines—and anionic heparin. A unique laboratory characteristic of HIT is that high heparin concentrations (10 to 100 units/mL) inhibit platelet activation by the pathogenic IgG[9]; this laboratory feature is exploited in diagnostic testing for HIT (see Diagnosis).

There is a characteristic timeline that underlies the HIT immune response (Fig. 135-2).[3] Formation of pathogenic IgG antibodies is surprisingly fast, even in patients who have never previously been exposed to heparin. Bacterial cell walls—which are negatively charged—bind PF4, and there is evidence that bacterial infection could be responsible for preimmunization against PF4-dependent antigens.[10] This could explain both the high frequency of anti-PF4/heparin immunization and of clinical HIT (i.e., HIT could represent a misdirected antibacterial immune response).[10] Although heparin-treated patients can form heparin-dependent antibodies of the IgM or IgA subclass, these are unlikely to cause HIT.[1-3]

Excess thrombin generation contributes to the pathogenesis of some of the unusual sequelae of HIT, which can include venous thromboembolism,[11] warfarin-associated venous limb gangrene,[12] and overt (decompensated) disseminated intravascular coagulation (DIC). Increased thrombin generation in HIT is triggered by the shedding of procoagulant microparticles from platelets activated by HIT antibodies, as well as by the expression of tissue factor by endothelial cells or monocytes activated by HIT antibodies (see Fig. 135-1).[13]

As noted, thrombocytopenia develops in only a minority of patients who form HIT antibodies.[1] The variable risk for HIT in different patient populations may reflect variations in the susceptibility of platelets to activation by HIT-IgG and/or differences in the levels and immunoglobulin class composition of HIT antibodies.[2,3] Poorly defined clinical factors also influence the risk for HIT, which occurs more often in surgical patients than in medical or obstetric patients.[6] Major trauma was more likely than minor trauma to be associated with HIT antibody formation and clinical HIT in one study.[14] There is indirect evidence that formation of stoichiometrically optimal complexes of PF4/heparin influences the risk for

Table 135-1 Risk Factors for Heparin-Induced Thrombocytopenia

Heparin type:	Unfractionated > low-molecular-weight heparin > fondaparinux
Patient type:	Postoperative (major > minor surgery) > medical > obstetric/pediatric
Dose*:	Prophylactic dose > therapeutic dose > flushes
Duration:	11-14 days† > 5-10 days > 4 days or fewer
Sex:	Female > male

*Importance of heparin dose is uncertain because of confounding effect of patient type (e.g., postoperative patients tend to receive prophylactic-dose heparin whereas medical patients [e.g., with venous thromboembolism] are more likely to receive therapeutic-dose heparin); nevertheless, reported frequencies of heparin-induced thrombocytopenia (HIT) are relatively high in patients given postoperative prophylactic-dose heparin.
†Heparin exposure beyond 14 days does not usually increase the risk of HIT beyond that of an 11- to 14-day exposure.

immunization.[15] The clinical situation influences the type of HIT-associated thrombosis: venous thromboembolism typically develops in orthopedic patients with HIT, whereas thrombosis develops equally often in arteries and in veins in cardiovascular patients with HIT.[1]

CLINICAL AND LABORATORY MANIFESTATIONS

Most patients with HIT have moderate thrombocytopenia; The median platelet count nadir is approximately 60×10^9/L; for 90% of patients, the platelet count nadir is greater than 20×10^9/L (Fig. 135-3).[16] In the rare patient whose platelet count falls to less than 10×10^9/L, there is often evidence of DIC, and red cell fragments and circulating normoblasts may be evident on examination of the blood smear. Thrombosis can occur in HIT patients when there is a 30% or greater decrease in the platelet count, even if the platelet count nadir never falls below 150×10^9/L.[1]

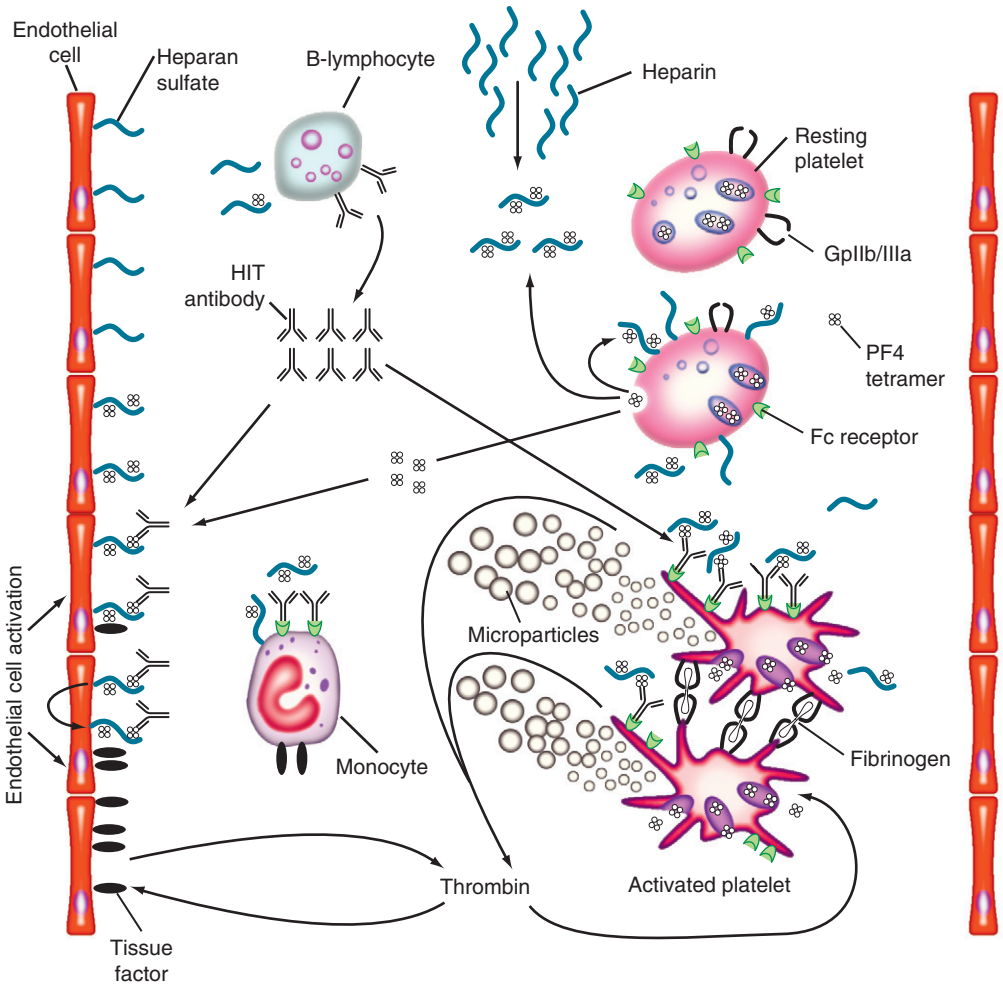

Figure 135-1 PATHOGENESIS OF HEPARIN-INDUCED THROMBOCYTOPENIA (HIT). Heparin produces mild platelet activation, resulting in release of platelet factor 4 (PF4) from platelet α-granules and the formation of immunogenic PF4/heparin complexes. B lymphocytes generate IgG immunoglobulins that recognize the PF4/heparin complexes; the Fc "tails" of the IgG bind to platelet FcγIIa receptors, resulting in Fc receptor clustering and consequent "strong" platelet activation. Platelet-derived microparticles are generated that accelerate thrombin generation. The HIT antibodies also recognize PF4 bound to endothelial heparan sulfate, leading to immunoinjury that causes endothelial activation. Recent evidence suggests that HIT antibodies also activate monocytes. The greatly increased thrombin generation observed in HIT helps to explain its association with venous and arterial thrombosis, as well as some of its unusual clinical features (e.g., warfarin-induced venous limb gangrene, decompensated disseminated intravascular coagulation), and also provides a rationale for treatments that control thrombin generation (e.g., with indirect [antithrombin-dependent] or with direct thrombin inhibitors). *(Reprinted with permission from Greinacher A, Warkentin TE: Treatment of heparin-induced thrombocytopenia: An overview. In Warkentin TE, Greinacher A, editors:* Heparin-induced thrombocytopenia, *ed 4, New York, 2007, Informa Healthcare USA, p 287.)*

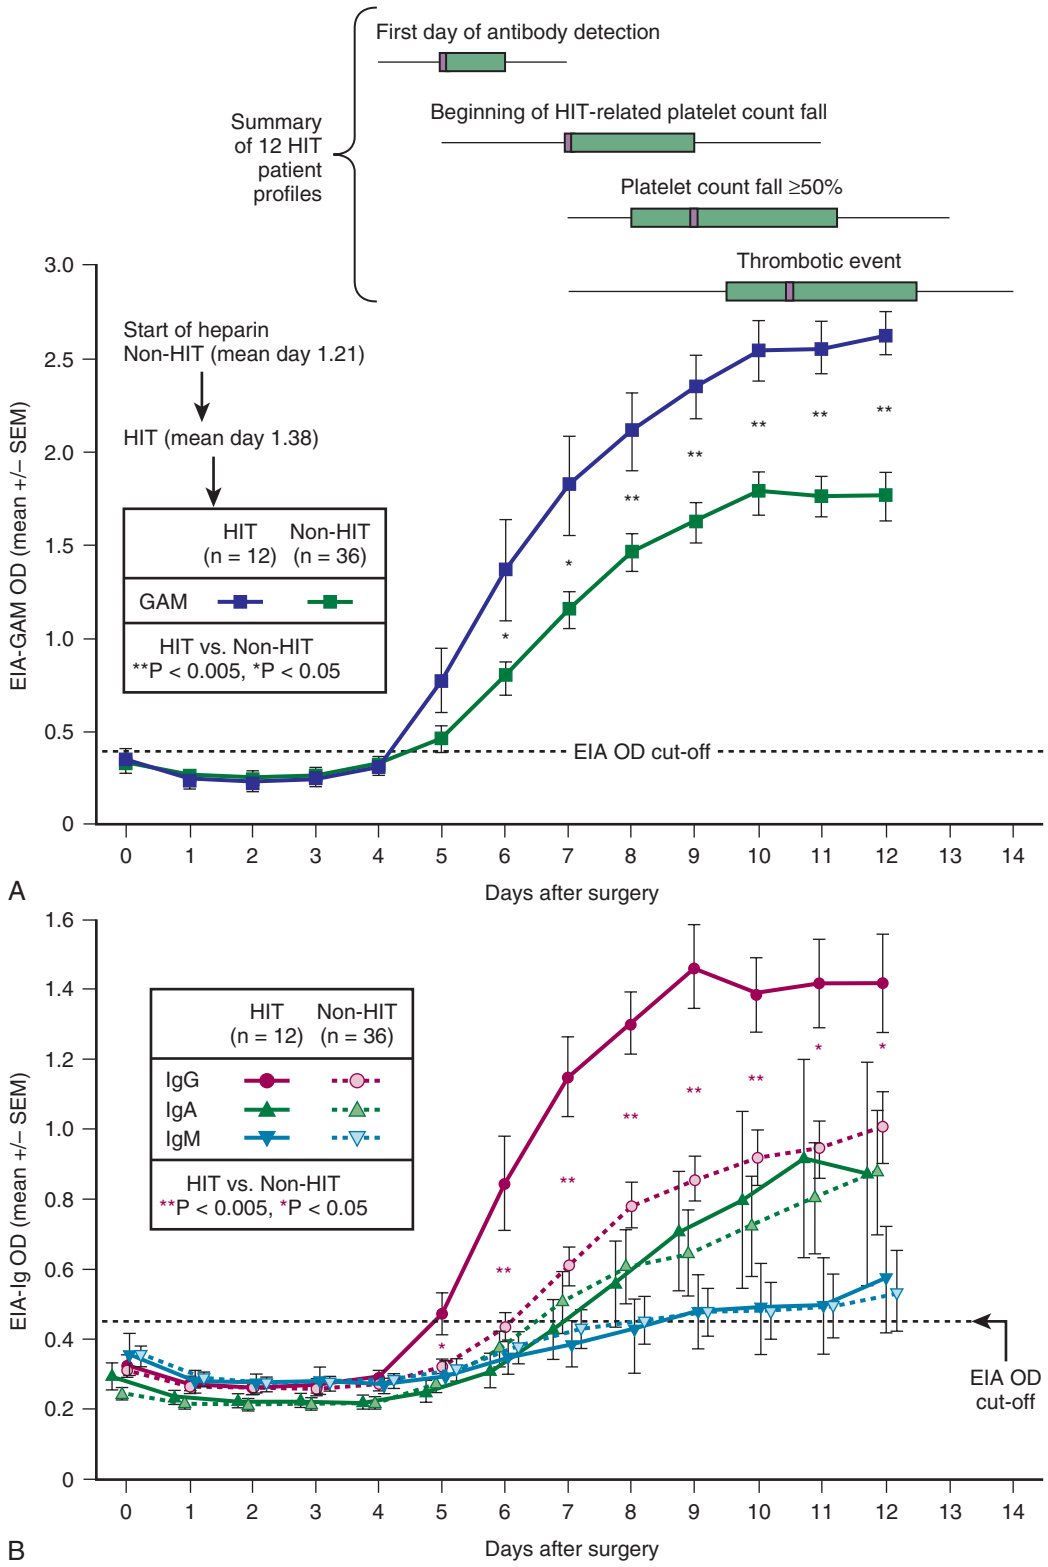

Figure 135-2 CHARACTERISTIC TIMELINE OF HEPARIN-INDUCED THROMBOCYTOPENIA (HIT). Anti-PF4/heparin antibodies (by enzyme immunoassay [EIA]) per postoperative day in 12 patients with HIT and 36 seropositive non-HIT control patients. **A,** Mean (±standard error of the mean [SEM]) optical density (OD) of anti-PF4/heparin antibodies detected using commercial immunoassay (EIA-GAM) that detects antibodies of all three immunoglobulin classes (IgG, IgA, IgM). HIT patients are indicated by —■—, and seropositive non-HIT controls by —■—. On each day beginning on postoperative day 6, there is a significant difference in the mean of the OD levels between the patients with HIT and the seropositive non-HIT controls ($P < .05$ by nonpaired t test). At the top of the figure, summary data for 12 HIT patient profiles are shown for four key events (first day of antibody detection, beginning of HIT-related platelet count fall, platelet count fall ≥50%, and thrombotic event), summarized as median *(small purple squares within rectangles),* interquartile range *(rectangles),* and range *(ends of thin black lines)*. **B,** Mean (±SEM) OD values of anti-PF4/heparin antibodies detected using an in-house immunoassay (EIA-Ig) that detects antibodies of the individual immunoglobulin classes, IgG *(red circles),* IgA *(green triangles),* and IgM *(blue inverted triangles)* for HIT *(solid symbols)* and non-HIT *(open symbols)*. On each postoperative day beginning on day 5, there is a significant difference in the mean of the OD units for the IgG immunoassay between the patients with HIT and the seropositive non-HIT controls (**$P < .005$ for days 6 to 10; *$P < .05$ for days 5, 11, and 12). *(From Warkentin TE, Sheppard JI, Moore JC, et al: Studies of the immune response in heparin-induced thrombocytopenia.* Blood *113:4693, 2009.)*

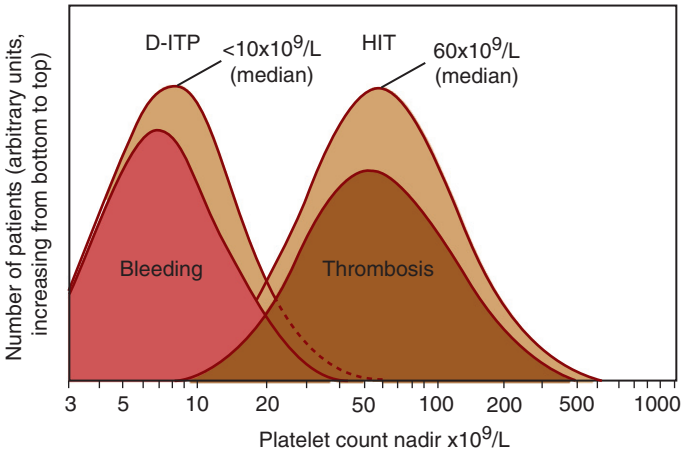

Figure 135-3 SEVERITY OF THROMBOCYTOPENIA IN DRUG-INDUCED IMMUNE THROMBOCYTOPENIA: A COMPARISON OF HEPARIN-INDUCED THROMBOCYTOPENIA (HIT) VERSUS OTHER DRUG-INDUCED IMMUNE THROMBOCYTOPENIA (DITP) DISORDERS. Whereas DITP is strongly associated with petechiae and purpura, HIT is strongly associated with thrombosis. Note: The heights of the DITP and HIT curves are not drawn to scale, because HIT is more common than all DITP disorders combined. *(From Warkentin TE: Drug-induced immune-mediated thrombocytopenia—from purpura to thrombosis.* N Engl J Med *356:891, 2007.)*

The platelet count fall usually begins 5 to 10 days after the initiation of an immunizing heparin exposure and while the patient continues to receive heparin (typical-onset HIT).[17] Usually the immunizing trigger is heparin given during surgery (e.g., cardiac or vascular surgery) or that is started soon after surgery (e.g., thromboprophylaxis). Interestingly, starting LMWH thromboprophylaxis before elective surgery (as is more frequently done in Europe) is less likely to be associated with antibody formation compared with postoperative first-dose administration.[15]

HIT is recognized in approximately one-quarter of patients when the platelet count fall occurs abruptly after restarting UFH or LMWH (rapid-onset HIT). Invariably, such patients have been exposed to heparin within the previous 5 to 100 days,[17] because HIT antibodies are transient and are only detectable for several weeks after an immunizing heparin exposure. Consequently, rapid-onset HIT—which is caused by administration of heparin to a patient with preformed HIT antibodies—is strongly associated with recent heparin exposure.

Sometimes, thrombocytopenia occurs several days after a brief exposure to heparin or worsens despite stopping heparin (delayed-onset HIT).[18,19] On exceptionally rare occasions, a transient prothrombotic disorder that resembles HIT clinically and serologically occurs without an apparent preceding heparin exposure ("spontaneous" HIT).[20] HIT is a highly prothrombotic condition: At least 50% of HIT patients develop thrombosis.[1,11,16] Both venous (deep vein thrombosis and/or pulmonary embolism) and arterial (especially aortic and iliofemoral arterial thrombosis, stroke, or myocardial infarction) thrombosis can occur.[11] Other complications include necrotizing skin lesions at the sites of subcutaneous heparin injection and acute inflammatory/cardiorespiratory (anaphylactoid) or transient memory disturbances after intravenous heparin bolus administration to sensitized persons. Unexplained hypotension or abdominal pain in a patient with HIT suggests bilateral adrenal hemorrhagic infarction, which can lead to acute adrenal failure; the hemorrhagic adrenal necrosis is the result of adrenal vein thrombosis.

Patients with HIT have an unusual predisposition to develop ischemic limb necrosis. Indeed, approximately 5% to 15% of such patients develop some degree of limb necrosis necessitating amputation. Occasionally multiple limbs are involved (see the box on Diagnostic Considerations in the Patient With Limb Ischemia and Thrombocytopenia).

Diagnostic Considerations in the Patient With Limb Ischemia and Thrombocytopenia

Concurrence of limb ischemia/necrosis and thrombocytopenia suggests one of several hematologic emergencies:

- **Heparin-induced thrombocytopenia (HIT).** Occlusion of large lower-limb arteries by platelet-rich "white clots" is characteristic of HIT. The major clue is an otherwise unexplained platelet count fall that begins 5 or more days after initiation of heparin. Urgent thromboembolectomy may be limb sparing. Sensitive assays for HIT antibodies give strongly positive results. See subsequent entry for warfarin.
- **Adenocarcinoma-associated disseminated intravascular coagulation (DIC).** Severe venous or arterial thrombosis can develop in patients with metastatic adenocarcinoma who have DIC. This often occurs within hours after stopping heparin. A clinical clue is an otherwise unexplained rise in platelet count that occurs with initial or repeated heparin therapy. See next entry for warfarin.
- **Warfarin-induced phlegmasia cerulea dolens/venous limb gangrene.** Coumarin anticoagulants, such as warfarin, can lead to venous ischemia (phlegmasia cerulea dolens) or venous limb gangrene in patients with DIC caused by HIT or adenocarcinoma. Limb loss can occur even though the limb pulses are palpable.
- **Sepsis-associated microvascular thrombosis.** Acquired natural anticoagulant depletion (e.g., markedly reduced antithrombin or protein C levels) can complicate DIC associated with sepsis, leading to acral limb ischemia or necrosis.
- **Septic embolism.** Rarely, infective endocarditis or aneurysmal thrombosis leads to the constellation of thrombocytopenia and acute limb ischemia.
- **Antiphospholipid syndrome.** Autoimmune thrombocytopenia and hypercoagulability can interact to produce acute limb ischemia and thrombocytopenia in patients with antiphospholipid syndrome.

DIFFERENTIAL DIAGNOSIS

Only approximately 10% of patients who undergo laboratory investigations for clinically suspected HIT have a serologic profile that supports the diagnosis (i.e., detectable heparin-dependent, platelet-activating IgG antibodies that recognize PF4/heparin complexes).[5] The differential diagnosis includes postoperative thrombocytopenia (hemodilution/platelet consumption), thrombocytopenia of critical illness, and septicemia. Some non-HIT disorders mimic HIT so closely that they warrant the term *pseudo-HIT*. One example of pseudo-HIT is adenocarcinoma-associated DIC, in which the combination of progressive thrombocytopenia and severe venous limb ischemia that occurs during the transitioning of patients from heparin (either UFH or LMWH) to warfarin may suggest a diagnosis of HIT.[21] Another disorder that can mimic HIT is the antiphospholipid syndrome: here, thrombocytopenia, thrombosis, and a false-positive PF4-dependent enzyme immunoassay (EIA) due to anti-PF4 (not anti-PF4/heparin) antibodies can be present.[22]

CLINICAL SCORING SYSTEMS

The pretest probability of HIT can be estimated using validated scoring systems. The 4 Ts system represents a mnemonic that is based on ***T***hrombocytopenia, ***T***iming (of onset of thrombocytopenia or thrombosis), ***T***hrombosis (or other clinical sequelae of HIT), and no o***T***her explanation for thrombocytopenia, with each of the 4 Ts scoring as an integer of 0, 1, or 2 points, based upon the likelihood of HIT (thus the maximum score is 8 points) (Table 135-2).[23] The presence of platelet-activating HIT antibodies is unlikely (< 3%) with

Table 135-2 4Ts Scoring System: Estimating the Pretest Probability of Heparin-Induced Thrombocytopenia

	Points (0, 1, or 2 for Each of Four Categories: Maximum Possible Score = 8)		
	2	*1*	*0*
Thrombocytopenia (acute)	Platelet fall > 50% (nadir ≥20 × 10^9/L) and no surgery within preceding 3 days	Nadir, 10-19 × 10^9/L; or any 30%-50% fall; or, > 50% fall within 3 days of surgery	Nadir, < 10 × 10^9/L; or any < 30% fall
Timing* of platelet count fall, thrombosis, or other sequelae	Clear onset between days 5-10; or ≤1 day (if prior heparin exposure in the past 5-30 days)	Consistent with day 5-10 fall, but not clear (e.g., missing platelet counts); or ≤1 day (heparin exposure within past 31-100 days); or platelet fall after day 10	Platelet count fall begins in ≤4 days without recent heparin exposure
Thrombosis or other clinical sequelae	New proven thrombosis; skin necrosis†; anaphylactoid reaction after IV heparin bolus; adrenal hemorrhage	Progressive or recurrent thrombosis; erythematous skin lesions†; suspected thrombosis (awaiting confirmation with imaging)	None
O**T**her cause for thrombocytopenia not evident	No other explanation for platelet count fall is evident	Possible other cause is evident	Definite other cause is present
Pretest probability score: 6-8 = HIGH; 4-5 = INTERMEDIATE; 0-3 = LOW			

Reprinted, with permission, from Warkentin TE: Clinical picture of heparin-induced thrombocytopenia. In Warkentin TE, Greinacher A, editors: *Heparin-induced thrombocytopenia*, ed 4, New York, 2007, Informa Healthcare USA, pp 21-66.
IV, Intravenous.
*First day of immunizing heparin exposure considered day 0; immunizing heparin is usually that given during or soon after surgery (e.g., unfractionated heparin [UFH] during cardiac surgery is more immunogenic than UFH given during preceding acute coronary syndrome or with heart catheterization); the day the platelet count *begins* to fall is considered the day of onset of thrombocytopenia.
†Skin lesions occurring at heparin injection sites.
The scoring system shown here has undergone minor modifications from previously published scoring systems.

a low score (≤3 points), but relatively probable (approximately 50%) with a high score (≥6). An intermediate score (4 or 5) indicates a clinical profile compatible with HIT, but also with other disorders, such as sepsis; here the frequency of platelet-activating HIT antibodies is still only approximately 10% to 20%.

A newer scoring system is called the HIT Expert Probability (HEP) score (Table 135-3).[24] In the initial evaluation (not yet independently validated), a HEP score of 4 points or higher indicated an approximately 50% probability of HIT, whereas a score of 3 points or lower was associated with only a 3% probability of HIT.

It is uncertain whether one scoring system offers advantages over the other. In general, low scores in either system indicate a low probability of HIT, whereas high scores indicate at most a 50:50 chance of HIT. Thus laboratory testing is crucial to establish a diagnosis of HIT.

LABORATORY DIAGNOSIS

Assays for HIT antibodies can be classified as platelet "activation" (or "functional") and PF4-polyanion "antigen" assays (or immunoassays). Activation assays that measure serotonin release from ^{14}C-labeled, washed platelets (i.e., the serotonin-release assay [SRA]) are quite sensitive and specific for detecting clinically significant HIT antibodies.[25] Important quality control maneuvers include the selection of platelet donors whose platelets respond well to Fc receptor stimulation, as well as the inclusion of negative and positive HIT sera of variable reactivity to ensure that the test platelets identify weaker HIT sera. The characteristic activation profile produced by HIT serum includes increased platelet activation at low heparin concentrations (0.05 to 0.3 units/mL), but background platelet activation at high heparin concentrations (10 to 100 units/mL).[9] Strong platelet activation induced by HIT sera even in the absence of pharmacologic heparin is a feature of delayed-onset HIT and may generally indicate more severe HIT.[18]

Three enzyme(-linked) immuno(sorbent) assays (EIAs or ELISAs) are commercially available for detecting antibodies that recognize PF4 bound to heparin, to the polyanion, polyvinyl sulfonate, or to PF4 (from platelet lysate) bound to protamine. These assays are very sensitive for detecting HIT antibodies but are much more likely than washed platelet activation assays to detect clinically insignificant anti-PF4/heparin antibodies.[2,3,5] Thus results of laboratory tests must be interpreted in the clinical context—that is, HIT is a "clinicopathologic" syndrome.[4] Activation and antigen assays are not 100% concordant, and there are advantages if reference laboratories are able to perform both types of assay. In general, serum or plasma from patients with clinical HIT have strongly positive assay results, whereas clinically insignificant antibodies give weaker results.[2,5] Indeed, if the EIA yields only a weakly positive result (e.g., 0.45 to 1.0 absorbance units), the corresponding probability of "true" HIT is 5% to 10% at most. In contrast, if the EIA yields a strongly positive result (> 2.0 units), the probability of HIT exceeds 90%.[5] Table 135-4[25] provides evidence from three studies supporting the greater diagnostic specificity of the SRA compared with the EIA: importantly, EIA+/SRA– status does *not* support a diagnosis of HIT.

PROGNOSIS

Approximately half of all patients with SRA+ HIT have clinically evident thrombosis at the time of initial diagnosis of HIT.[11] Among patients without thrombosis at diagnosis, there appears to be a high risk (approximately 25% to 50%) for subsequent thrombosis if heparin is simply discontinued.[11] It is increasingly accepted that further anticoagulation is indicated in most patients strongly suspected as having "isolated" HIT[26,27]—that is, HIT recognized because of thrombocytopenia rather than because of HIT-associated thrombosis.

THERAPY

Although it is standard practice to discontinue heparin in patients strongly suspected of having HIT, including stopping heparin "flushes" of intravascular catheters (with substitution of saline flushes), heparin cessation is not necessarily beneficial, for two reasons: (1) heparin likely has an anticoagulant effect even in patients with HIT, and (2) HIT antibodies often cause ongoing platelet activation

Table 135-3 HIT Expert Probability (HEP) Scoring System

Clinical Feature	Score
1. Magnitude of fall in platelet count (measured from peak platelet count to nadir platelet count since heparin exposure)	
a. < 30%	–1
b. 30%-50%	1
c. > 50%	3
2. Timing of fall in platelet count	
For patients in whom typical-onset HIT is suspected	
a. Fall begins < 4 days after heparin exposure	–2
b. Fall begins 4 days after heparin exposure	2
c. Fall begins 5-10 days after heparin exposure	3
d. Fall begins 11-14 days after heparin exposure	2
e. Fall begins > 14 days after heparin exposure	–1
For patients with previous heparin exposure in last 100 days in whom rapid-onset HIT is suspected	
f. Fall begins < 48 hr after heparin reexposure	2
g. Fall begins > 48 hr after heparin reexposure	–1
3. Nadir platelet count	
a. ≤ 20×10^9/L	–2
b. > 20×10^9/L	2
4. Thrombosis (Select no more than one)	
For patients in whom typical-onset HIT is suspected	
a. New VTE or ATE ≥ 4 days after heparin exposure	3
b. Progression of preexisting VTE or ATE while receiving heparin	2
For patients in whom rapid-onset HIT is suspected	
c. New VTE or ATE after heparin exposure	3
d. Progression of preexisting VTE or ATE while receiving heparin	2
5. Skin necrosis	
a. Skin necrosis at subcutaneous heparin injection sites	3
6. Acute systemic reaction	
a. Acute systemic reaction after intravenous heparin bolus	2
7. Bleeding	
a. Presence of bleeding, petechiae, or extensive bruising	–1
8. Other causes of thrombocytopenia (Select all that apply)	
a. Presence of a chronic thrombocytopenic disorder	–1
b. Newly initiated nonheparin medication known to cause thrombocytopenia	–2
c. Severe infection	–2
d. Severe DIC (defined as fibrinogen < 100 mg/dL and D-dimer > 5.0 mcg/mL	–2
e. Indwelling intra-arterial device (e.g., IABP, VAD, ECMO)	–2
f. Cardiopulmonary bypass within previous 96 hr	–1
g. No other apparent cause	3

Reprinted, with permission, from Cuker A, Arepally G, Crowther MA, et al: The HIT Expert Probability (HEP) Score: A novel pre-test probability model for heparin-induced thrombocytopenia based on broad expert opinion, *J Thromb Haemost* 8:2642, 2010.
ATE, Arterial thromboembolism; *DIC,* disseminated intravascular coagulation; *ECMO,* extracorporeal membrane oxygenation; *HIT,* heparin-induced thrombocytopenia; *IABP,* intra-aortic balloon pump; *VAD,* ventricular assist device; *VTE,* venous thromboembolism. In its initial evaluation, a HEP score of ≥4 points indicated an approximately 50% probability of HIT, whereas a score of ≤3 points was associated with only a 3% probability of HIT.

Table 135-4 Frequency of Thrombocytopenia (> 50% Platelet Count Fall) Among EIA+ Patients (Polyspecific or IgG-Specific Assay) Who Received Heparin (UFH or LMWH): A Comparison of SRA+ versus SRA– Status

SRA Status	Positive in Polyspecific EIA (IgG/A/M)	Positive in IgG-Specific EIA
A. Post–orthopedic surgery		
SRA+	12/24	12/24
SRA–	0/58	0/16
P	< 0.0001	0.0009
B. Venous thromboembolism		
SRA+	4/4	4/4
SRA–	0/15	0/6
P	0.0003	0.0048
C. Post–cardiac surgery		
SRA+	4/11	NA
SRA–	0/152	NA
P	< 0.0001	NA

EIA, Enzyme immunoassay; *LMWH,* low-molecular-weight heparin; *NA,* not available; *SRA+,* positive in the serotonin-release assay; *SRA–,* negative in the serotonin-release assay; *UFH,* unfractionated heparin.
The data are consistent with the SRA having a high sensitivity for heparin-induced thrombocytopenia (> 95%); the specificity of the SRA depends on the clinical situation but in most circumstances is at least 90%. Patients in studies A and B were tested in both the polyspecific and IgG-specific assays.

and hypercoagulability in the absence of pharmacologic heparin. In addition, HIT antibody levels can decline even with continued heparin. The recognition that patients with HIT have increased thrombin generation[12] provides a rationale for use of nonheparin anticoagulant agents that rapidly inhibit thrombin or its generation.

Currently there are two types of anticoagulant therapeutic approaches that are commonly used to treat HIT: (1) long-acting indirect (i.e., antithrombin-dependent) factor Xa inhibitors (danaparoid, fondaparinux), and (2) direct thrombin inhibitors (recombinant hirudin, argatroban, bivalirudin).[19] In the author's opinion, indirect factor Xa inhibitors—although not approved in the United States for treatment of HIT—are the preferred treatment option for HIT, because they have numerous advantages over DTIs (Table 135-5).[19] In addition, because approximately 90% of patients suspected of HIT do not have HIT,[5] another advantage for indirect factor Xa inhibitors is that these agents—unlike DTIs—are safe and effective for prevention and treatment of thrombosis in numerous non-HIT settings.

Indirect Factor Xa Inhibitors: Danaparoid and Fondaparinux

Danaparoid is an anticoagulant heparinoid (mixture of glycosaminoglycans) with predominant inhibitory activity against factor Xa that is effective for treating HIT; however, danaparoid was never approved for HIT treatment in the United States (although it was approved in many other countries, including Canada and the European Union) and was discontinued in the United States in April 2002. Danaparoid was shown to be safe and effective for treatment of HIT in an open-label randomized controlled trial (versus dextran 70) and in a retrospective comparison against ancrod (defibrinogenating snake venom) and/or vitamin K antagonist therapy.

In recent years, however, physicians have increasingly been using fondaparinux as off-label therapy for HIT. The advantages of fondaparinux include its long half-life, the fact that it does not require coagulation monitoring nor does it influence the aPTT or international normalized ratio (INR), its low potential to cross-react with HIT antibodies, and low cost. In addition, because relatively few patients with suspected HIT actually have this diagnosis, the wide experience with fondaparinux and its approval for the prevention and treatment of thrombosis in non-HIT settings constitute other advantages. To date, the experience with fondaparinux to treat HIT has been favorable, including the treatment of patients with SRA+ HIT (Table 135-6).[28-33] Also, fondaparinux is much less likely than UFH or LMWH to precipitate rapid-onset HIT in patients who have unrecognized HIT antibodies.[34] Although fondaparinux thromboprophylaxis has been associated with rare cases of de novo HIT,[28] this should not deter from its use as a potential treatment of HIT because the potential to trigger immunization is "dissociated" from whether an

Table 135-5 Comparison of the Two Classes of Anticoagulants Used to Treat Heparin-Induced Thrombocytopenia

	Indirect (AT-Dependent) Factor Xa Inhibitors: Danaparoid, Fondaparinux	Direct Thrombin Inhibitors: r-Hirudin (Lepirudin, Desirudin), Argatroban, Bivalirudin
Half-life	√ Long (danaparoid, 25 hr*; fondaparinux, 17 hr): reduces risk of rebound hypercoagulability	Short (< 2 hr): potential for rebound hypercoagulability
Dosing	√ Both prophylactic- and therapeutic-dose regimens†	Prophylactic-dose regimens are not established (exception: subcutaneous desirudin)
Monitoring	√ Direct (anti-Xa levels): accurate drug levels obtained	Indirect (aPTT): risk for DTI underdosing due to aPTT elevation caused by non-DTI factors, including HIT-associated DIC
Effect on INR	√ No significant effect: thus simplifies overlap with warfarin	Increases INR: argatroban > bivalirudin > r-hirudin; complicates warfarin overlap
Protein C pathway	√ Adverse effect unlikely (with reduced thrombin generation, there will be less thrombin to activate protein C)	Thrombin inhibition could impair thrombin-mediated activation of protein C pathway
Reversibility of action	√ Irreversible inhibition: AT forms covalent bond with factor Xa	Irreversible inhibition only with r-hirudin
Efficacy and safety in non-HIT settings	√ Treatment and prophylaxis of VTE (danaparoid, fondaparinux) and ACS (fondaparinux)	Not established for most non-HIT settings (exception: bivalirudin established for PCI)
Platelet activation	√ Danaparoid inhibits platelet activation by HIT antibodies	No effect
Inhibition of clot-bound thrombin	No effect	√ Inhibition of both free and clot-bound thrombin
Drug clearance	Predominantly renal	Variable (predominantly hepatobiliary: argatroban; predominantly renal: r-hirudin)
Cost	√ Relatively low‡	Relatively high‡

Reprinted, with modifications, with permission, from Warkentin TE: Agents for the treatment of heparin-induced thrombocytopenia, *Hematol Oncol Clin North Am* 24:755, 2010.
ACS, Acute coronary syndrome; *aPTT,* activated partial thromboplastin time; *AT,* antithrombin; *DIC,* disseminated intravascular coagulation; *DTI,* direct thrombin inhibitor; *HIT,* heparin-induced thrombocytopenia; *INR,* international normalized ratio; *PCI,* percutaneous coronary intervention; *VTE,* venous thromboembolism.
Check mark (√) indicates favorable feature in comparison of drug classes (author's opinion).
*For danaparoid, half-lives of its anti-thrombin (anti-IIa) and its thrombin generation inhibition activities (2-4 hr and 3-7 hr, respectively) are shorter than for its anti-Xa activity (approximately 25 hr).
†Although therapeutic dosing is recommended for HIT, availability of prophylactic-dose regimens increases flexibility when managing potential non-HIT situations.
‡Another cost consideration is that a patient can be discharged to home on subcutaneous danaparoid or fondaparinux, whereas an additional 5-7 in-hospital days may be required for DTI-warfarin overlap before discharge from hospital.

Table 135-6 Fondaparinux for Treatment of Acute Heparin-Induced Thrombocytopenia

Study	N	N With HITT (%)	Mean Platelet Count Nadir ($\times 10^9$/L)	Thrombosis Rate	Amputation Rate*	Major Bleeding
Kuo and Kovacs[29]	5	5 (100%)	43	0%	0%	0%
Lobo et al[30]	7	6 (86%)	66	0%	1/7 (14%)	0%
Grouzi et al[31]	24	14 (58%)	66†	0%	1/24 (4%)	0%
Warkentin et al[32]	16	9 (56%)	79	0%	1/16 (6%)	1/16 (6%)
Goldfarb and Blostein[33]	8	6 (75%)	56	0%	0%	0%
Pooled data (above five studies)	60	40 (67%)	66	0/60 (0%)	3/60 (5%)	1/60 (2%)

HITT, Heparin-induced thrombocytopenia and thrombosis (in this context, the thrombosis preceded treatment with fondaparinux).
*In all patients with limb amputations, ischemic limb necrosis was judged to have been present before fondaparinux therapy.
†The mean platelet count nadir excludes two patients with myeloproliferative disorder who had baseline thrombocytosis.

anticoagulant potentiates antibody-induced platelet activation,[7] and fondaparinux has low potential to exacerbate HIT.[34] Dosing information for danaparoid and fondaparinux is shown in Table 135-7.

In theory, oral direct factor Xa inhibitors, such as rivaroxaban (approved in the United States for thromboprophylaxis after knee or hip replacement surgery), should be effective for treatment of HIT. However, there is no experience with rivaroxaban for this indication as of yet.

Direct Thrombin Inhibitors: Recombinant Hirudin (Lepirudin, Desirudin), Bivalirudin, Argatroban

The recombinant hirudin–derivative lepirudin (Refludan) is a 65-amino-acid polypeptide that inactivates thrombin by forming a tight, noncovalent 1:1 complex with it. Lepirudin is approved for the treatment of HIT-associated thrombosis in the European Union, the United States, and elsewhere.[26] Lepirudin is renally excreted, and the drug must be avoided (or the dosage substantially reduced) in patients with renal failure. With normal renal function, the half-life of intravenously administered lepirudin is about 80 minutes. Coagulation monitoring is performed using the aPTT (target aPTT, 1.5 to 2.5 times the baseline value). In the treatment of HIT-associated thrombosis, lepirudin reduced a composite end point (encompassing new thrombosis, limb amputation, and all-cause mortality) from 40.0% (in historical controls) to 19.2% (pooled data from the HAT-1, -2, and -3 trials; analysis from start of treatment).[26] The end point of new thrombosis was reduced from 25.3% to 7.0%. Major bleeding complications were seen in about 15% of patients

Table 135-7 Treatment Schedules for Danaparoid and Fondaparinux

Anticoagulant	Therapeutic Dosing Protocol for HIT-Associated Thrombosis*	Anticoagulant Monitoring	Clearance	Half-life (hr)	Comment
Danaparoid	Initial bolus, 2250 units† IV; accelerated infusion (400 units/hr × 4 hr, 300 units/hr 4 hr; then 200 units/hr IV, subsequently adjusted by anti–factor Xa levels)	Anti–factor Xa levels (target, 0.5-0.8 units/mL)	Renal (minor)	25	Widely approved for HIT treatment (although not in the United States); not available in the United States; low risk for in vivo cross-reactivity; prophylactic-dose therapy‡ may be appropriate when clinical suspicion for HIT is low
Fondaparinux	7.5 mg§ subcutaneous once daily	Anti–Xa factor levels (target levels not well established)	Renal (major)	17	Not approved for HIT treatment (although increasingly used as off-label therapy). Prophylactic-dose therapy‖ may be appropriate when clinical suspicion for HIT is low, or if there is renal insufficiency

HIT, Heparin-induced thrombocytopenia; *IV,* intravenous.
*Therapeutic dosing is usually appropriate for strongly suspected or confirmed HIT (including "isolated" HIT, i.e., HIT without apparent thrombosis), or when thrombosis is documented.
†Adjust IV danaparoid bolus for body weight: < 60 kg, 1500 units; 60-75 kg, 2250 units; 75-90 kg, 3000 units; > 90 kg, 3750 units.
‡Prophylactic-dose regimen, 750 units subcutaneous every 8 hr (for renal failure, reduce to 750 units every 12 hr).
§Five milligrams for body weight < 50 kg and 10 mg for body weight > 100 kg; the author sometimes gives 10 mg as the first and/or second dose (rather than 7.5 mg) for severe HIT. Because HIT treatment is usually started in the afternoon, the author usually gives the second dose (and subsequent doses) at 8 AM (i.e., the interval between first and second doses is often only 14-20 hr rather than 24 hr), which helps to achieve steady-state therapy more quickly. Dose reduction and anti–factor Xa monitoring (if available) is appropriate if being used in a patient with renal insufficiency.
‖Prophylactic-dose regimen, 2.5 mg subcutaneous every day (assumes normal renal function).

(compared with 6.7% in historical controls), or approximately 1% per treatment day. The high rate of bleeding prompted recommendations to administer initial doses lower than those recommended in the package insert, even in patients with normal renal function.[26] In patients with isolated HIT (an off-label indication), lepirudin given in "prophylactic" doses (0.1 mg/kg/hr intravenously without an initial bolus, and adjusted to an aPTT of 1.5 to 2.0 times baseline) was associated with new thrombosis in only 4.4% of patients. This lower-dose regimen also seems appropriate for patients with HIT-associated thrombosis.[26] Similarly low rates of thrombosis have been observed in postmarketing studies of treatment of lepirudin for isolated HIT. Fatal anaphylactic reactions have been reported in patients reexposed to lepirudin. These reactions occur in as many as 1 in 400 patients after intravenous bolus administration. This is another reason to avoid bolus dosing in most clinical situations. The manufacturer discontinued lepirudin (April, 2012), but it may remain available in some jurisdictions via another manufacturer.

Another recombinant hirudin, desirudin (Iprivask) is available in the United States, where it is marketed for thromboprophylaxis after hip replacement surgery (dose, 15 mg twice daily by subcutaneous injection in patients with normal renal function). There is minimal experience with desirudin in patients with HIT.

Bivalirudin (Angiomax) is a 20-amino-acid thrombin inhibitor modeled after hirudin that is composed of two peptide fragments that recognize the active site of thrombin and its fibrinogen-binding site, linked by a tetraglycine spacer. The half-life of bivalirudin is about one-third that of lepirudin (25 versus 80 minutes), and only minor dose adjustments are needed in patients with renal insufficiency because bivalirudin is only partially cleared by the kidneys. It is approved as an alternative to heparin in patients undergoing percutaneous coronary intervention (PCI), including those with HIT. Its short half-life and predominantly extrarenal elimination are reasons why it is an option for intraoperative anticoagulation in patients undergoing cardiac surgery, when heparin is contraindicated because of acute or recent HIT. Experience using bivalirudin off-label to treat HIT outside the PCI setting is limited. Anaphylaxis has not been reported.

Argatroban (marketed as argatroban in the United States and as Novastan elsewhere) is a small-molecule (527-Da) Direct thrombin inhibitor (DTI) that undergoes predominantly hepatobiliary excretion and is therefore suitable for use without dose adjustment in patients with renal failure (the dose is reduced by three-quarters in patients with hepatic insufficiency). Argatroban is approved in the United States for both treatment and prevention of thrombosis in HIT. It is given in the same dosage for both indications (usual starting infusion rate of 2 mcg/kg/min without an initial bolus). However, as with lepirudin, lower starting doses are usually given (e.g., 0.5 to 1.2 mcg/kg/min), especially in critically ill patients. Argatroban (in substantially higher doses) is also approved for anticoagulation during PCI in patients with acute HIT or a history of HIT. Its half-life is 40 to 50 minutes. Argatroban prolongs the INR more than lepirudin or bivalirudin, and a higher-than-usual target INR during warfarin cotherapy (which depends on the thromboplastin reagent used to measure the INR) can be expected (see Caveats in Treatment of Heparin-Induced Thrombocytopenia). Argatroban reduced the frequency of a composite end point (new thrombosis, limb amputation, and all-cause mortality) from 56.5% (in historical controls) to 43.8% and 41.5% in two studies of patients with HIT complicated by thrombosis; new thrombosis event rates were reduced from 34.8% to 19.4% and 13.1%, respectively.[26] In patients with isolated HIT, argatroban reduced the rate of new thrombosis from 22.4% to 6.9%, and the combined event rate of new thrombosis, limb amputation, and all-cause mortality from 38.8% to 26.9%.[26] Dosing information for the parenteral DTIs is shown in Table 135-8.

In theory, dabigatran, an oral thrombin inhibitor, should also be effective for treatment of HIT. However, the drug has not yet been tested for this indication.

Caveats in Treatment of Heparin-Induced Thrombocytopenia

Warfarin and other vitamin K antagonists (coumarins) should not be used during the acute thrombocytopenic phase of HIT.[12] A particularly high-risk situation is HIT associated with deep vein thrombosis, especially if there is overt (decompensated) DIC. If such patients are treated with warfarin, there is a risk for progression to venous limb gangrene.[12,26,27] The laboratory marker for this unusual syndrome is a high INR (generally, greater than 4.0), which corresponds to the combination of a marked reduction in the level of protein C together with increased thrombin generation (as evidenced by elevated levels of thrombin-antithrombin complexes) during warfarin therapy.[12] Although warfarin (in theory) should be safe in a patient whose

Table 135-8 Treatment Schedules for Lepirudin, Desirudin, Bivalirudin, and Argatroban

Anticoagulant	Dosing Protocol for HIT-Associated Thrombosis	Anticoagulant Monitoring*	Clearance	Half-Life (min)	Comment
Lepirudin	No bolus; initial infusion rate: 0.05-0.10 mg/kg/hr[†‡]	1.5-2.5 × baseline aPTT	Renal[‡]	80	Approved dosing regimen (not shown) is too high; risk for anaphylaxis, especially on reexposure; minor prolongation of INR (compare to argatroban)
Desirudin	Not established	aPTT	Renal	120	Half-life shown is for subcutaneous administration; minimal experience for treating HIT
Bivalirudin	No bolus; initial infusion rate: 0.15-0.20 mg/kg/hr	1.5-2.5 × baseline aPTT	Enzymic (80%); renal (20%)	25	Off-label treatment for HIT (although approved for PCI in patient with HIT); minor prolongation of INR (compared with argatroban)
Argatroban	No bolus; initial infusion rate: 2 mcg/kg/min	1.5-3.0 × baseline aPTT	Hepatobiliary	40-50	Initial dose 0.5 mcg/kg/min in hepatic insufficiency[§]; moderate or marked prolongation of INR, which complicates overlap with warfarin anticoagulation

aPTT, Activated partial thromboplastin time; *HIT,* heparin-induced thrombocytopenia; *INR,* international normalized ratio; *PCI,* percutaneous coronary intervention. Dosing protocols shown are appropriate for most patients with strongly suspected or confirmed HIT whether or not complicated by thrombosis. (Dosing for bivalirudin and argatroban is substantially different when given for PCI.)

*Generally the patient's baseline aPTT should be used for calculating target range, when appropriate; otherwise the mean laboratory normal range can be used.

[†]This dosing protocol differs from the package insert (which advises initial bolus of 0.4 mg/kg and initial infusion rate [assuming normal renal function] of 0.15 mg/kg/hr); however, this dosing regimen is now considered too high.[26]

[‡]Major dose reduction in renal insufficiency is required (e.g., lepirudin starting infusion rate, 0.05 mg/kg/hr for serum creatinine 90-140 μmol/L; starting infusion rate, 0.01 mg/kg/hr for serum creatinine 140 to 400 μmol/L; and starting infusion rate 0.005 μmol/L for serum creatinine > 400 μmol/L, with frequent aPTT monitoring [every 4 hr until steady state is achieved, then at least once daily]).[26]

[§]Reduced initial dosing (e.g., 0.5-1.2 mcg/kg/min) is also appropriate in patients in intensive care units, with cardiac failure, or post–cardiac surgery).

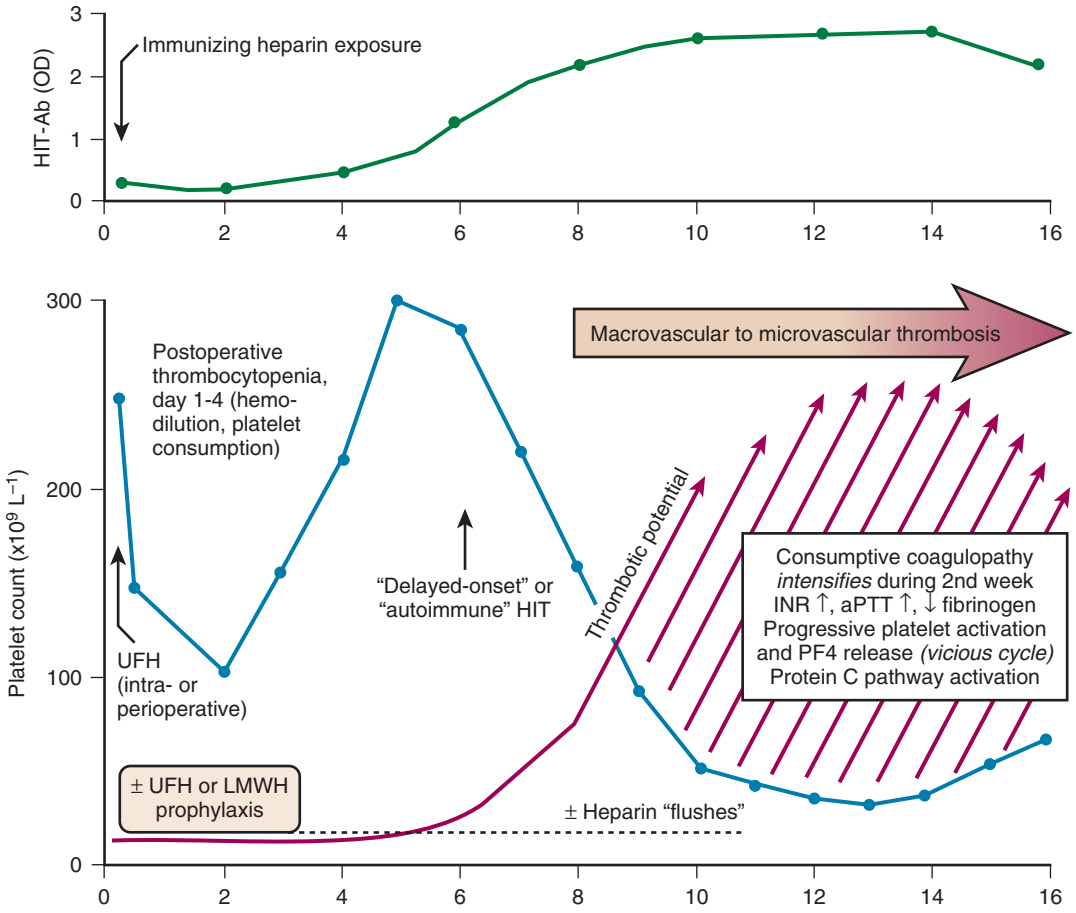
thrombin generation is controlled (e.g., using a DTI), it is important to delay the initiation of warfarin until there is substantial resolution of the thrombocytopenia (to more than 150×10^9/L).[26,27] Warfarin treatment should be delayed because its prolongation of the aPTT may result in *underdosing* of the DTI, and because stopping the DTI before resolution of the HIT during warfarin overlap can lead to limb loss due to fulminant venous limb gangrene.[4,19]

Several case observations suggest that aPTT confounding of DTI therapy can be a factor explaining progression of thrombosis in patients with severe HIT.[4,19] For example, patients can develop progressive thrombocytopenia and HIT-associated consumptive coagulopathy despite stopping heparin (Fig. 135-4). In such patients, aPTT monitoring of DTI therapy can fail because a brief course of DTI can abruptly lead to supratherapeutic aPTT levels—not because of anticoagulant overdosing but because of the combination of DTI and consumptive coagulopathy—and interruption/cessation of DTI therapy can be associated with rapid progression of microvascular thrombosis. In this setting, factor Xa inhibitors (danaparoid, fondaparinux) may be more effective because they do not require aPTT monitoring. Alternatively, DTI levels can be measured directly, but these assays are rarely performed in North American laboratories.

Using sensitive assays for HIT antibodies, LMWH reacts similarly to UFH in vitro. Furthermore, because LMWH can lead to worsening of clinical HIT, these agents should not be used to treat HIT.[26,27]

Although primary treatment for HIT should include an anticoagulant that inhibits thrombin or reduces its generation, certain treatment adjuncts can be used in special situations. These include surgical thromboembolectomy, high-dose intravenous immunoglobulin, antiplatelet drugs such as aspirin, and plasmapheresis.

These caveats, along with recommendations for management of patients with suspected HIT, are summarized in the box on Diagnosis and Treatment of Heparin-Induced Thrombocytopenia.



PREVENTION

The frequency of platelet count monitoring in patients receiving heparin should reflect the overall risk of HIT (i.e., the preparation, the dose, and the clinical situation).[26] At least alternate-day platelet count monitoring should be considered in patients at relatively high risk for developing HIT (e.g., after orthopedic or cardiac surgery). Monitoring at least two or three times a week should be considered for patients at moderate risk for developing HIT (e.g., medical patients receiving UFH, postoperative patients receiving UFH flushes or LMWH). The frequency of HIT is low with LMWH,[1,6] particularly in medical patients or during pregnancy, and routine platelet count monitoring may not be required in such settings.[26] In addition, HIT rarely begins 14 or more days after initiation of a course of heparin,[17] so routine monitoring beyond this period is not required. A recent consensus conference[27] recommended somewhat less intensive platelet count monitoring than advised in this paragraph.

ANTICOAGULATION AND PREVIOUS HEPARIN-INDUCED THROMBOCYTOPENIA

HIT antibodies are transient and usually are undetectable several weeks or a few months after an episode of HIT.[17] If HIT antibodies are no longer detected, it is appropriate to use heparin for a brief indication in situations where other anticoagulants have drawbacks (e.g., cardiac surgery).[17,26,27] Heparin should be avoided preoperatively (e.g., argatroban or bivalirudin can be used for heart catheterization). Patients with acute or recent HIT who require urgent heart surgery and still have detectable antibodies have been successfully treated with alternate anticoagulant approaches (e.g., bivalirudin, lepirudin, or heparin plus an antiplatelet agent such as epoprostenol or tirofiban), but each of these approaches has disadvantages. For example, the high dose of lepirudin regimen needed for cardiac surgery requires monitoring with the ecarin clotting time, a test that is not widely available, and patients can develop severe bleeding if renal failure occurs; epoprostenol causes hypotension, and there is limited experience with its use in cardiac surgery. Bivalirudin is the most promising agent for use in cardiac surgery, but special surgical and anesthesiologic maneuvers are required (because bivalirudin undergoes proteolysis, thus posing a risk for clotting of stagnant blood in the extracorporeal circuit).

A diagnostic and therapeutic approach to HIT[23] is shown in the box on Diagnosis and Treatment of Heparin-Induced Thrombocytopenia.

Indirect (AT-mediated) factor Xa inhibitors (danaparoid, fondaparinux)	1. Long half-life achieves stable levels of anticoagulation. 2. No interference with activation of the protein C pathway. 3. Specific assays accurately measure drug levels (anti-Xa activity). 4. Inhibition of HIT-Ab-induced platelet activation (danaparoid only).
Direct thrombin inhibitors (DTIs) (hirudin, argatroban, bivalirudin)	1. PTT monitoring can be unreliable, e.g., DIC, liver disease, warfarin. 2. Short half-lives — risk for "rebound" hypercoagulability. 3. Interfere with thrombin-induced activation of protein C pathway. 4. Reversible DTIs (argatroban, bivalirudin) could block thrombin inhibition by AT.
Vitamin K antagonists (warfarin, acenocoumarol, phenprocoumon)	1. Vitamin K antagonists do not inhibit thrombin or its generation. 2. Predispose to protein C depletion (vitamin K–dependent factor). 3. Raise the PTT, thus risking DTI underdosing or interruption. 4. Long half-lives, thus any adverse effects could persist for days.

Figure 135-4 CONCEPTUAL FRAMEWORK OF HEPARIN-INDUCED THROMBOCYTOPENIA (HIT): FOCUS ON HEPARIN-*IN*DEPENDENT PLATELET ACTIVATION AND DELAYED-ONSET ("AUTOIMMUNE") HIT. The *upper panel* shows the timeline of HIT antibody (HIT-Ab) formation, as judged by optical density (OD) units in an anti–platelet factor 4 (PF4)/polyanion enzyme immunoassay (EIA). The *middle panel* illustrates a platelet count decline in the absence of heparin (or with small amounts of heparin, e.g., heparin flushes) indicating delayed-onset HIT, with intensification of HIT-associated hypercoagulability from day 7 to 14, especially after stopping heparin. Patients with this clinical profile often have HIT-associated consumptive coagulopathy (overt disseminated intravascular coagulopathy [DIC]), and are at risk for confounding of activated partial thromboplastin time (aPTT)-monitored direct thrombin inhibitor (DTI) treatment. The *lower panel* compares different classes of anticoagulant for expected effects on HIT-associated hypercoagulability, including the risk for aPTT confounding in the setting of HIT-associated DIC. *AT,* Antithrombin; *INR,* international normalized ratio; *LMWH,* low-molecular-weight heparin; *PTT,* partial thromboplastin time; *UHF,* unfractionated heparin. *(From Warkentin TE: Agents for the treatment of heparin-induced thrombocytopenia.* Hematol Oncol Clin North Am *24:755, 2010.)*

Diagnosis and Treatment of Heparin-Induced Thrombocytopenia

Heparin-induced thrombocytopenia (HIT) should be clinically suspected when thrombocytopenia occurs during (or soon after) heparin therapy and the temporal profile of the decrease in platelet count is consistent with immune sensitization to heparin. Four relevant questions—the 4 Ts—should be asked:

***T*hrombocytopenia:** Does the patient have thrombocytopenia? A greater than 50% fall in the platelet count can indicate HIT even if the platelet count has not fallen to below 150×10^9/L. (Note: Severe thrombocytopenia, such as a platelet count below 10×10^9/L, is rarely caused by HIT.)

***T*iming:** Is the timing of the platelet count fall consistent with immune sensitization? In HIT the platelet count usually begins to fall 5 to 10 days after starting heparin (first day of heparin is day 0); a more rapid fall in the platelet count can occur if the patient is already sensitized from heparin exposure within the past 100 days.

***T*hrombosis:** Does the patient have thrombosis or other sequelae of HIT? (Note: In addition to venous and arterial thrombosis, patients with HIT can develop necrotizing skin lesions at heparin injection sites or systemic inflammatory or cardiorespiratory reactions that begin 5 to 30 minutes after an intravenous [IV] heparin bolus).

O*T*her: Are there other explanations for the thrombocytopenia? HIT is less likely when there is compelling clinical evidence for another cause of the thrombocytopenia, such as positive blood cultures.

Steps in Management of Clinically Suspected Heparin-Induced Thrombocytopenia

1. Confirm that thrombocytopenia is present (repeat complete blood cell count [CBC]), test for disseminated intravascular coagulation (DIC), and test for HIT antibodies, preferably using a platelet activation test such as the serotonin-release assay (SRA).
2. Assess clinically and radiologically for thrombosis (e.g., compression ultrasound for lower-limb deep venous thrombosis).
3. Stop all heparin, including heparin flushes and possibly use of heparin-coated intravascular catheters (catheters left in situ for several days may not have much residual heparin).
4. Initiate treatment with an alternative anticoagulant, generally in therapeutic doses if HIT is strongly suspected (options: danaparoid,*† fondaparinux,*‡ lepirudin,§ argatroban, bivalirudin*).
5. Although initial treatment decsions are made on clinical grounds, results of testing for HIT antibodies can influence subsequent treatment, including the decision to resume heparin if HIT has been ruled out using one or more sensitive assays for HIT antibodies.

Caveats

- Do not use low-molecular-weight heparin to treat HIT.
- Do not start (or continue) warfarin or other coumarins until the platelet count has returned to normal (greater than 150×10^9/L), and give only in low initial doses (warfarin, 5 mg or less) and overlap with a parenteral anticoagulant for at least 5 days.
- Do give vitamin K (e.g., 5 to 10 mg IV over 30 to 60 minutes) if HIT is diagnosed after warfarin has already been given, so as to reduce risk for coumarin necrosis and to avoid underdosing of direct thrombin inhibitor (DTI) because of activated partial thromboplastin time (aPTT) prolongation by warfarin.
- Beware of confounding of aPTT-monitored DTI therapy in patients with severe HIT complicated by HIT-associated consumptive coagulopathy (DIC) or who have other explanations for an elevated aPTT, such as warfarin therapy, liver disease, or antiphospholipid syndrome.
- Do not give prophylactic platelet transfusions (platelet transfusions are appropriate if the patient is bleeding or if there is diagnostic uncertainty).

*Not approved for treatment of HIT in the United States (except, in the case of bivalirudin, for anticoagulation during percutaneous coronary intervention).
†Withdrawn from the U.S. market, but available in many other countries.
‡Fondaparinux is not approved for treatment of HIT, but case series suggest that it is at least as effective as DTI therapy; moreover, the risk for bleeding with fondaparinux is likely to be lower than that with DTI therapy and fondaparinux costs less than the other agents. Also, there is greater experience with fondaparinux than DTIs for prevention and treatment of thrombosis in non-HIT situations, and only approximately 10% of patients with suspected HIT actually have the disorder. Fondaparinux also avoids the risk for confounding of aPTT-monitored DTI therapy. The author is a proponent of the use of fondaparinux to treat HIT.[25,28,32,34]
§Lepirudin discontinued by the manufacturer, April 2012; however, it may continue to be available through another manufacturer (Cellgene, U.K.)/distributor (Pharmore, Germany).

CHAPTER 136

THROMBOTIC THROMBOCYTOPENIC PURPURA AND THE HEMOLYTIC UREMIC SYNDROME

Keith R. McCrae, J. Evan Sadler, and Douglas B. Cines

In 1925, Moschowitz described a 16-year-old girl who died of a previously undescribed illness characterized by microangiopathic hemolytic anemia, petechiae, hemiparesis, and fever. Postmortem examination revealed numerous hyaline thrombi, most prevalent in the terminal arterioles and capillaries of the heart and kidneys. In 1936, four similar cases were reported by Baehr and colleagues, who proposed that the hyaline thrombi were secondary to agglutinated platelets; in 1947, Singer suggested that the term *thrombotic thrombocytopenic purpura (TTP)* be used to describe this disorder. In 1955, Gasser used the term *hemolytic uremic syndrome (HUS)* to describe a related syndrome that consisted of Coombs-negative hemolytic anemia, thrombocytopenia, and renal failure. These disorders are now referred to as *thrombotic microangiopathies (TMA),* based on their shared features of microangiopathic hemolytic anemia, thrombocytopenia, and microvascular thrombotic lesions.

Although the clinical and pathologic features of TTP and HUS may overlap, recent scientific advances have demonstrated that the pathogenesis of these disorders differs. Several pathogenesis-based classification schemes for thrombotic microangiopathies have been developed; one example incorporated in recent guidelines developed by the British Committee for Standard in Haematology and the British Transplantation Society is illustrated (Table 136-1).

EPIDEMIOLOGY

Thrombotic Thrombocytopenic Purpura

Idiopathic TTP (not precipitated by a defined event or exposure) occurs with an estimated annual incidence of 3.7 to 11 cases per million, but it appears to be increasing, perhaps the result of increased awareness. TTP has a female/male ratio of 3:2 and a peak incidence in the fourth decade. Additional risk factors include obesity and African ancestry, which is also associated with an increased risk for relapse. Nonidiopathic TTP (defined as TTP associated with a known precipitant, such as hematopoietic stem cell transplant [HSCT]) appears to be more common. TTP occurs in 1 in 1600 to 1 in 5000 individuals treated wih ticlopidine. In contrast, the estimated incidence of TTP is 12 per million clopidogrel-treated patients. Other drugs associated with nonidiopathic TTP include the calcineurin inhibitors gemcitabine and mitomycin-C, as well as quinine, cyclosporine, and tacrolimus.

HSCT-associated TTP affects between 0.5% and 76% of transplant patients. The wide variation in incidence likely reflects diagnostic uncertainty and a lack of universally accepted criteria, as well as the effects of posttransplant infection, DIC, and other morbidities that mimic TTP. Pregnancy is another common precipitating factor for TTP (12% to 31% of individuals). TTP develops most frequently in the second or third trimester, with the decrease in ADAMTS13 levels and increase in von Willebrand factor (vWF) and factor VIII that occur in normal pregnancy perhaps acting as precipitants. TTP has also been reported in approximately 0.3% of HIV-infected patients, usually in those with advanced disease.

Congenital TTP, also known as *Upshaw-Schülman syndrome,* is considerably less common than idiopathic TTP. A recent study describing the natural history of congenital TTP in Japan identified 43 cases ranging in age from childhood to 79 years. Of these cases, 42% were diagnosed during childhood, 36% between the ages of 15 and 45 (all female, most commonly presenting during pregnancy), and 12% beyond age 45.

Hemolytic Uremic Syndrome

Two primary variants of HUS are described based on epidemiologic patterns. Most common is "typical" HUS, often referred to as *Stx-HUS* because of its association with infection by bacteria that express Shiga or Shiga-like toxins. "Atypical" HUS may occur in sporadic or familial patterns.

Stx-HUS

Stx-HUS ("typical," "epidemic," "childhood," diarrhea-associated, or Shiga toxin–producing *E. coli* [STEC]–associated) accounts for at least 90% of all cases. In one study conducted in the United States, the median age of patients with Stx-HUS was 4 years; 55% of patients were younger than 5 years of age, 33% between 5 and 17 years, 6% between 18 and 44 years, and 6% older than 45 years of age. STEC accounts for 80% to 86% of cases in the United States and Europe. The major reservoir of STEC is domestic cattle; approximately 2% to 3% harbor STEC in their gastrointestinal tract at the time of slaughter, and meat can become contaminated during processing. The organism has also been isolated from deer, sheep, goats, horses, dogs, birds, and flies. Outbreaks are often associated with ingestion of inadequately cooked ground beef, although contamination of poultry, cheese, fruits, and vegetables has also been reported. Other cases have been attributed to ingestion of contaminated water or unpasteurized apple cider or milk. The incidence of Stx-HUS may be increasing as a result of developments in food-production methods. Industrial farming generates large quantities of potentially contaminated manure that periodically enters streams, where it can contaminate feed and uncooked vegetables. A recent outbreak of HUS in Northern Germany that affected more than 3000 individuals was caused by STEC O104:H4; the reservoir of pathogenic *E coli* was bean sprouts with evidence of intrahousehold transmission. Carriage of STEC may be asymptomatic, and fecal-oral transmission may contribute to spread in day care centers, nursing homes, and petting zoos. Aerosolization in barns has been implicated in outbreaks at fairs.

The relationship of Stx to human disease was first recognized in 1983 based on the identification of *E. coli* strain O157:H7 as the cause of two outbreaks of hemorrhagic gastroenteritis. Over 100 additional STEC strains have been identified. STEC strains are also associated with sporadic, nonepidemic cases of HUS. The disease occurs more frequently during summer and autumn in temperate climates. Infection by Shiga toxin–producing *Shigella dysenteriae* serotype 1 is associated with HUS in developing countries and carries a higher mortality.

Table 136-1 Proposed Classification Scheme for Thrombotic Microangiopathies

ADVANCED UNDERSTANDING OF ETIOLOGY
Infection induced
Shiga and verocytotoxin (Shiga-like toxin)–producing bacteria
Streptococcus pneumoniae
Disorders of complement regulation
Genetic disorders of complement regulation
Acquired disorders of complement regulation, for example anti-FH antibody
ADAMTS13 abnormalities
ADAMTS13 deficiency secondary to mutations
Autoantibodies against ADAMTS13
Defective cobalamine metabolism
Quinine induced
ETIOLOGY NOT FULLY UNDERSTOOD
HIV
Malignancy
Drugs
Pregnancy
Systemic lupus erythematosus and antiphospholipid antibody syndrome

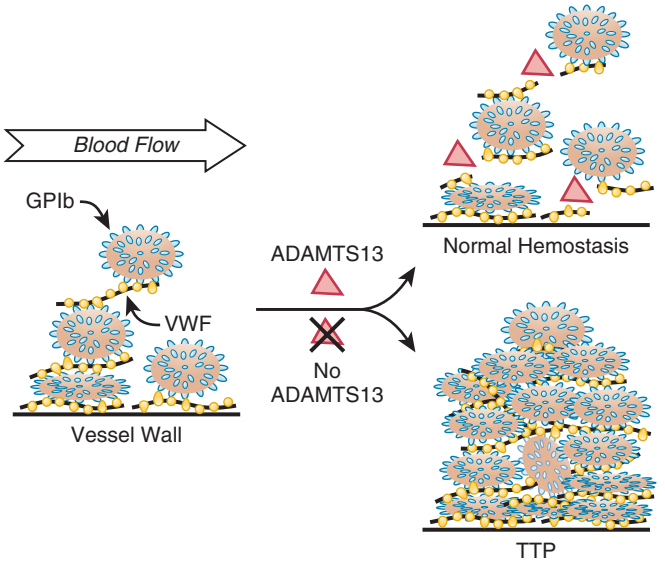

Figure 136-1 PATHOGENESIS OF IDIOPATHIC THROMBOTIC THROMBOCYTOPENIC PURPURA CAUSED BY ADAMTS13 DEFICIENCY. Multimeric vWF adheres to endothelial cells or to connective tissue exposed in the vessel wall. Platelets adhere to vWF through platelet membrane GP1b. In flowing blood, vWF in the platelet-rich thrombus *is stretched* to form extended linear polymers and cleaved by ADAMTS13, limiting thrombus growth. If ADAMTS13 is absent, vWF-dependent platelet accumulation continues, eventually causing microvascular thrombosis and TTP. *(Reproduced from Sadler JE: von Willebrand factor, ADAMTS13, and thrombotic thrombocytopenic purpura.* Blood *112:11, 2008, with permission.)*

Atypical HUS (aHUS)

aHUS is a form of systemic TMA in which renal failure develops in the absence of an obvious precipitating factor. Although sometimes referred to as "adult" HUS, 60% of cases occur in children. However, aHUS only accounts for 5% to 10% of all childhood HUS. Seventy percent of children have their first episode before 2 years of age, 25% of these developing before 6 months, an age at which Stx-HUS is very uncommon. Childhood aHUS is equally prevalent in males and females, with a slight female preponderance in adults. Though aHUS is generally not associated with a prodrome of bloody diarrhea, a history of recent gastroenteritis may be obtained from up to 30% of patients. Abnormalities in complement regulation, most commonly due to mutations in complement regulatory proteins, have been implicated in 70% of cases. Inheritance is autosomal with approximately 50% penetrance. TMA that complicates bone marrow transplantation, immunosuppressive medication, and chemotherapy resembles aHUS, although it is likely that the pathogenesis of these other disorders differs.

Though aHUS is less common than TTP, the fact that up to 16% of patients included in large TTP series required dialysis demonstrates that these disorders can be indistinguishable on clinical grounds. The incidence of aHUS in the United States has been estimated at 2 per million. More than 1000 patients with aHUS investigated for complement abnormalities have been identified through registries in Europe and the United States.

PATHOBIOLOGY

TMA is a syndrome in which different pathogenic pathways lead to vascular endothelial injury. In Stx-HUS, endothelial injury is caused by Shiga toxin and inflammatory cytokines, perhaps inciting disease with increased frequency in individuals with specific genetic predispositions. In most patients with TTP or aHUS, an inciting event may not be obvious but may involve viral infections, surgery, or other perturbations in vascular function and inflammation.

TTP

Most patients with TTP exhibit inherited or acquired deficiency of ADAMTS13, leading to increased levels of "unusually large" vWF multimers that induce platelet aggregation in the microvasculature. Endothelial cells secrete unusually large vWF multimers that may adhere to cell surfaces and promote platelet attachment or enter the circulation and promote intravascular platelet aggregation. Under high shear, vWF multimers elongate along the endothelium and promote platelet adhesion through interactions with platelet glycoprotein (GP) Ib; shear stress–induced conformational changes also enhance the susceptibility of vWF to enzymatic cleavage. ADAMTS13 regulates the activity of vWF by cleaving the most hemostatically active high-molecular-weight multimers; failure of this feedback mechanism may lead to the microvascular thrombosis, tissue ischemia, and infarction characteristic of TTP (Fig. 136-1). However, the factors that trigger sporadic episodes of TTP by causing endothelial damage or activation remain undefined. Moreover, some patients develop TTP despite normal levels of circulating ADAMTS13, while patients with congenital deficiencies of ADAMTS13 may not develop TTP until adulthood, or not at all. The latter observations suggest that ADAMTS13 deficiency should be considered an important predisposing factor, but not the sole cause of this syndrome. This concept is supported by studies of ADAMTS13-deficient mice, in which a TTP-like syndrome develops spontaneously in some genetic backgrounds (high vWF levels) but requires a triggering factor, such as Shiga toxin, in other strains.

Inherited ADAMTS13 Deficiency

Upshaw-Schülman syndrome is an autosomal recessive form of TTP first linked to vWF by Moake, who found unusually large vWF multimers in the plasma of patients with chronic relapsing TTP. He proposed that the patients lacked a plasma enzyme that cleaves these unusually large multimers and that the abnormal multimers then

caused uncontrolled intravascular platelet aggregation, thrombosis, and tissue infarction. Subsequently, a plasma metalloprotease was discovered that degrades vWF multimers by cleaving the Tyr[1605]-Met[1606] bond in the vWF subunit that is lacking in patients with Upshaw-Schülman syndrome.

The vWF protease has been purified from plasma, cloned, and found to be a member of the ADAMTS (a disintegrin-like and metalloprotease [reprolysin type] with thrombospondin type 1 motif) family of metalloproteases (Fig. 136-2). Genome-wide linkage analysis showed that Upshaw-Schülman syndrome is caused by mutations in the ADAMTS13 gene on chromosome 9q34.

ADAMTS13 is synthesized mainly by hepatic stellate cells but also in vascular endothelial cells and renal glomerular podocytes. Small amounts of functional ADAMTS13 are present in platelets. Deletion, splice site, frameshift and missense mutations that cause Upshaw-Schülman syndrome have been found in almost all structural domains of ADAMTS13 (see Fig. 136-2). Expression studies have shown that missense mutations usually prevent the secretion of ADAMTS13, although some also impair catalytic activity.

Acquired ADAMTS13 Deficiency

Almost all patients with nonfamilial, idiopathic TTP have an acquired severe reduction or absence of ADAMTS13 activity (<5%), usually associated with autoantibody IgG inhibitors. Some of the reported variation in ADAMTS13 activity levels may reflect inclusion or exclusion of patients with acute renal failure or other preexisting conditions. For example, severe ADAMTS13 deficiency was found in 18 of 48 adults with idiopathic TMA unselected for renal function, but it was seen in 22 of 22 patients without acute anuric renal failure. Acquired severe ADAMTS13 deficiency (<5%) is rare in other settings, with the possible exception of severe hepatic insufficiency or sepsis. For example, ADAMTS13 levels below 5% were found in 17 of 109 patients with sepsis-induced DIC. More modest decreases (typically >40%) occur in newborns and among adults with cirrhosis, chronic renal insufficiency, pregnancy, connective tissue diseases, and various inflammatory conditions; none had levels below 6%. Therefore severe ADAMTS13 deficiency appears to be specific for TTP in the appropriate clinical setting.

Antibodies against ADAMTS13 have been reported in 59% to 100% of patients with acquired severe ADAMTS13 deficiency. This variability probably reflects differences in assay sensitivity. Some antibodies promote ADAMTS13 clearance without inhibiting activity.

Other Mechanisms of Potential Relevance to TTP

ADAMTS13 levels are normal in some cases of idiopathic TTP, and in almost all cases of TMA associated with stem cell or organ transplantation, cancer, infections, severe hypertension, and certain drugs. Therefore mechanisms other than ADAMTS13 deficiency can cause thrombotic microangiopathy, and various studies have implicated direct endothelial injury, platelet activation, and alterations in blood clotting as contributory factors. Evidence in support of these mechanisms include the demonstration of (1) increased levels of circulating endothelial proteins (thrombomodulin, PAI-1, vWF) and endothelial cell microparticles in TTP plasma; (2) circulating antiplatelet and antiendothelial cell antibodies, some of which may bind CD36 and impair ADAMTS13 binding to endothelial cells; (3) increased levels of circulating platelet-derived microparticles; (4) induction of microvascular endothelial cell apoptosis by plasma from patients with idiopathic, HIV-associated, or ticlopidine-associated TTP; (5) increased

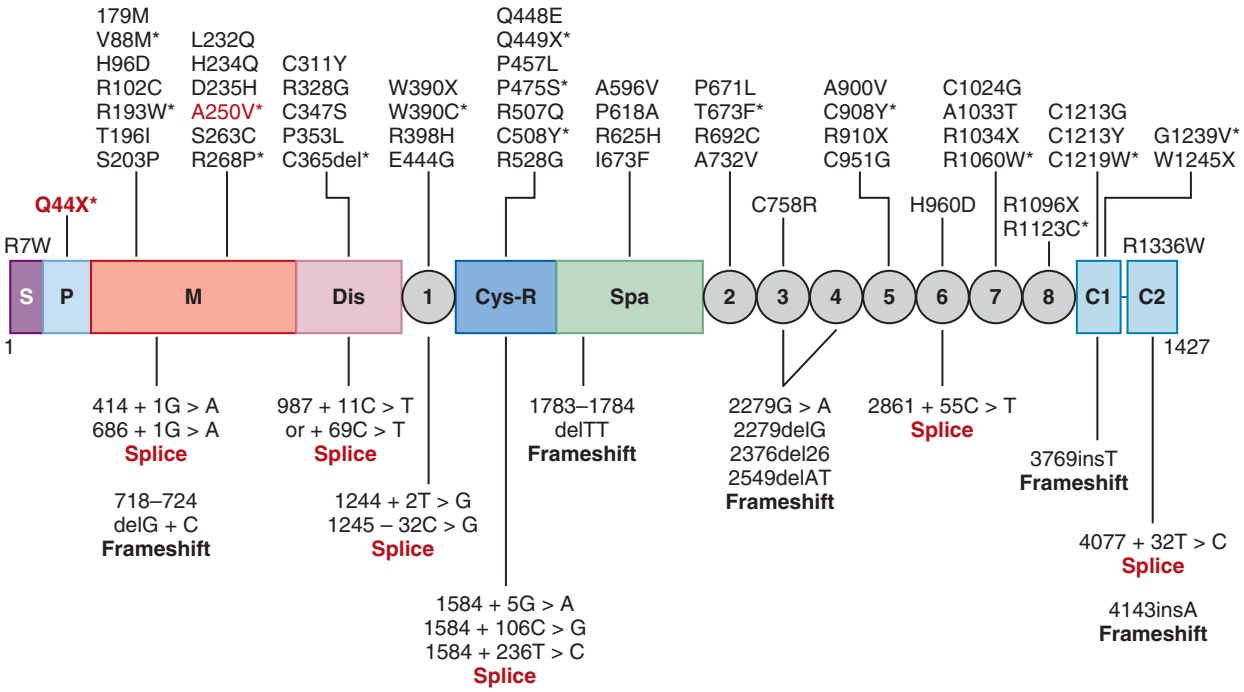

Figure 136-2 ADAMTS13 STRUCTURE AND LOCATION OF THE MUTATIONS FOUND IN PATIENTS WITH CONGENITAL THROMBOTIC THROMBOCYTOPENIC PURPURA. The point mutations that cause single amino acid substitutions and premature stop codons *(X)* are shown above the domain structure of ADAMTS13. The mutations that result in alternative splicing of *ADAMTS13* mRNA or frameshifts are listed under the domain structure of ADAMTS13. Those mutants expressed as recombinant proteins in cell culture *(*)* cause defects in ADAMTS13 secretion *(black)* or catalytic activity *(red)*. S, Signal peptide; P, propeptide; M, metalloprotease; Dis, disintegrin domain; 1, the first thrombospondin type 1 (TSP1) repeat; Cys-R, cysteine-rich domain; Spa, spacer domain; 2 through 8, the second to eighth TSP1 repeats; C1 and C2, the CUB domains 1 and 2. *(Reproduced from Zheng XL, Sadler JE: Pathogenesis of thrombotic microangiopathies.* Annu Rev Pathol *3:249, 2008.)*

plasma procoagulant activity; (6) increased endothelin and decreased nitric oxide, leading to vasoconstriction; and (7) diminished plasma fibrinolytic activity due to elevated levels of PAI-1.

Stx-HUS

HUS is caused by endothelial cell damage initiated by Shiga toxins and the inflammatory cytokines they induce. The type of Stx, as well as other virulence factors, contributes to risk.

The most common serotype of *E. coli* associated with HUS is O157:H7, although other serotypes including O26:H11, O103:H2, O111:NM, O21:H19, O145:NM, and O104:H4 have been reported. Enteropathic *E. coli* bacteria are noninvasive. After ingestion, organisms colonize the terminal ilium and follicle-associated epithelium of Peyer patches, after which they colonize the colon. Cross-talk between STEC and other commensal intestinal flora enhance STEC proliferation; these bacteria also respond to the host hormonal milieu, including elevated levels of epinephrine and norepinephrine that stimulate production of virulence factors by activating bacterial membrane histidine sensor kinases QseC and QseE. Once colonization is established, STEC bacteria express numerous virulence factors by horizontally transmitted gene cassettes termed *pathogenicity islands*. One pathogenicity island contains the locus of enterocyte effacement (LEE), which contains genes for the adhesin intimin, as well as a type III (three) secretion system (TTSS) that mediates transfer of bacterial proteins directly into enterocytes. These and other factors enable enteropathic bacteria to create a zone of tight attachment to the intestinal wall and enhance their proliferation. Their capacity to cause HUS is mediated by two 70-kD bacterial exotoxins named *verotoxins* for their cytotoxicity against African green monkey kidney (Vero) cells. The toxins are transported across the intestinal epithelium through specific para- and intercellular mechanisms and then circulate, most likely by binding with low affinity to the surface of neutrophils and platelets, before being transferred to receptors expressed on glomerular endothelial cells that are upregulated by proinflammatory cytokines.

Verotoxin-1 is identical to a Shigella toxin and is therefore generally referred to as *Shiga-like toxin 1 (SLT-1* or *Stx1).* Most strains of pathogenic *E. coli* produce a second homologous toxin, Stx2, which is associated with a higher risk for HUS. The toxins are carried on a lysogenic bacteriophage capable of infecting other strains of *E. coli*. Intact, 70-kD Stx holotoxins consist of a 32-kD A subunit and five 7.7-kD B receptor-binding subunits. The toxin binds to terminal Gala1-4Galb (galabiose) residues on globosyltriaosylceramide (Gb_3; also known as *CD77* and the human blood group P^k *antigen*) that are highly expressed on capillary endothelium in the glomerulus and brain; the expression of these receptors is upregulated by tumor necrosis factor-alpha (TNFα) released as a consequence of toxin-induced leukocyte activation. Increased expression of Gb_3 on glomerular microvascular and cerebral endothelium compared with other vascular beds contributes to their heightened sensitivity to apoptosis, cytotoxicity, upregulation of integrins, and procoagulant activity. The predilection of children to develop HUS may relate to the higher levels of Gb_3 expression in children compared with adults.

Following binding to Gb_3, the holotoxin is internalized and transported in a retrograde manner to the endoplasmic reticulum and translocated into the cytosol. The A subunit is proteolyzed to a 27-kD A1 subunit that binds the 60S ribosomal subunit and cleaves adenine 4323 from the 28S ribosomal RNA. This prevents elongation factor 1-dependent binding of aminoacyl tRNA, which inhibits protein synthesis and leads to endothelial cell apoptosis.

E. coli lipopolysaccharide and Stx also stimulate leukocyte and intrarenal expression of proinflammatory cytokines (including IL-1, -6, and -8; MCP-1; interleukin-1β; and interferon-γ) that exacerbate toxin- and leukocyte-induced endothelial dysfunction. Interactions between endothelial cell fractalkine and mononuclear leukocytes expressing the fractalkine receptor, CX(3)CR1, may play an important role in renal damage. Stx also acts in concert with lipopolysaccharide to trigger a procoagulant state early in the course of the disease that involves platelet activation, expression of tissue factor, release of unusually large vWF multimers, and elaboration of plasminogen activator-1.

Signal transduction through cross-linked B-unit/CD77 complexes may also contribute to cytotoxicity of the holotoxin. Recent studies demonstrated that both the Stx 1B and 2B subunits directly induce release of vWF from endothelial cells. Though Stx 1B binds Gb_3 with greater affinity than Stx 2B, the latter is a more potent inducer of endothelial cell vWF release, consistent with its ability to activate a different signaling pathway and its ability to induce acute TMA in ADAMTS13−/− mice.

Additional virulence factors, such as a cytolethal distending toxin that may interfere with the endothelial cell cycle, have been described, although their role in pathogenesis is undefined.

Atypical Hemolytic Uremic Syndrome

The pathogenesis of aHUS reflects aberrant activation of the alternative complement pathway leading to endothelial damage, resulting from mutations that lead to loss or functional impairment of complement regulatory proteins, or less commonly, activating mutations in alternative complement proteins. Such mutations have been detected in 70% of patients with aHUS and are transmitted in an autosomal manner, accounting for the commonly observed familial inheritance pattern, although disease penetrance is only 50%.

Complement may be activated via the classical (CP), alternative (AP) or lectin (LP) pathways. The AP plays an important role in protecting the intravascular space against bacterial infection and depends on potent amplification loops (Fig. 136-3). The AP is in a constant low-level activation state due to spontaneous hydrolysis of the thioester bond in C3, and regulation by complement inhibitory proteins is required to prevent pathologic activation and complement-mediated injury to host tissues. C3b is deposited on cell membranes, where an amplification loop consisting of complement factor B, factor D, and properdin leads to the deposition of additional C3b on the cell surface and the generation of the C3b convertase (C3bBbP) that further amplifies C3b generation. In the presence of an additional C3b, this convertase can also cleave C5 to C5a and C5b, leading to formation of the lytic C5b-C9 complex. Complement activation is regulated primarily by the plasma protein factor H, or the membrane-associated cofactor protein (MCP; CD46), each of which binds to membrane bound C3b, after which another plasma protein, factor I, cleaves and inactivates C3b. Another membrane-associated protein, decay-accelerating factor (DAF; CD55) accelerates the inactivation of C3 convertase, although mutations of DAF have not been shown to play a role in aHUS.

Mutations in several complement regulatory proteins predispose to aHUS. Mutations in factor H account for 30% of cases. Loss of function mutations have been identified throughout the protein, most commonly in the C-terminal short consensus repeats (SCRs) 19 and 20, which mediate cell binding (Fig. 136-4). These mutants have reduced capacity to regulate complement activation on platelet and endothelial cell surfaces and subendothelial basement membrane, though not necessarily in plasma; thus plasma C3 and C4 levels may not mirror cell surface pathophysiologic events. The factor H gene *(CFH)* lies in the regulators of complement activation (RCA) cluster at 1q32 close to five factor H–related proteins (*CFHR* 1-5). The latter contain multiple duplicated segments with homology to *CFH*. Thus the RCA is prone to nonallelic homologous recombination; this may lead to formation, for example, of a hybrid gene consisting of the first 21 exons of factor H (encoding the first 18 SCRs) and the last 2 exons of CFHR1 (encoding SCR 19 and 20), which has been associated with aHUS. In addition to genetic abnormalities of factor H, acquired deficiencies account for 5% to 10% of aHUS; these are most commonly due to inhibitory antibodies that recognize SCR 19 and 20 of factor H and occur in patients with deletions of *CFHR1* and *CFHR3*. The autoantibodies may cross react with factor H SCR 19 and 20 and CFHR1 SCR 4 and 5, which share extensive homology.

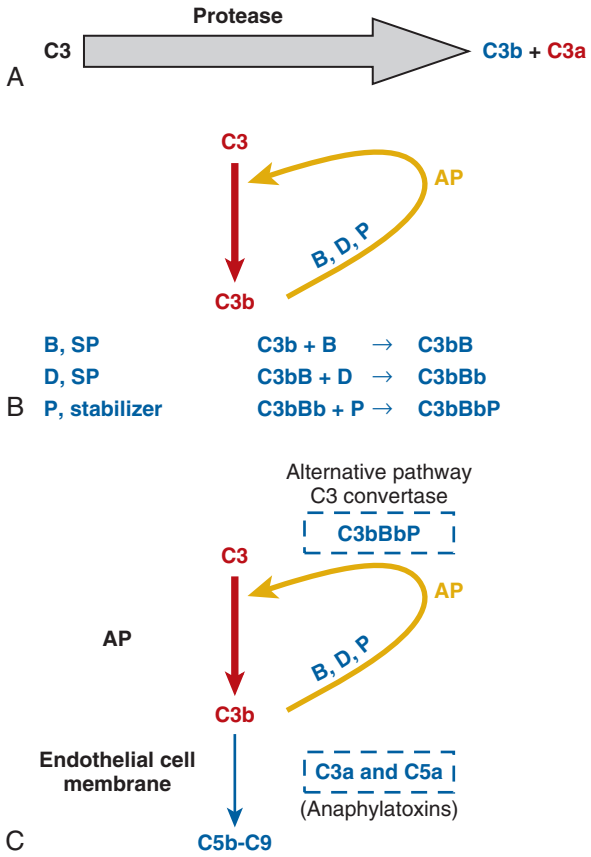

Figure 136-3 THE ALTERNATIVE PATHWAY OF COMPLEMENT ACTIVATION. **A,** The AP of the complement system originally consisted of a serine protease that cleaved C3 to the opsonin C3b and the proinflammatory anaphylatoxin C3a. **B,** An amplification loop was next evolved to more efficiently deposit C3b on a target and liberate C3a into the surrounding milieu. *B* indicates factor B; *D* indicates factor D, a serine protease; *P* indicates properdin, a stabilizer of the enzyme. **C,** Development of a C5 convertase. The same enzyme that cleaves C3 (AP C3 convertase) can cleave C5 to C5a and C5b with the addition of a second C3b to the enzyme complex (AP C5 convertase). *(From Liszewski MK, Atkinson JP: Too much of a good thing at the site of tissue injury: The instructive example of the complement system predisposing to thrombotic microangiopathy.* Hematology Am Soc Hematol Educ Program *2011:9, 2011, with permission.)*

Mutations in MCP are observed in approximately 15% of patients with aHUS. MCP is present on the surface of all nucleated cells except erythrocytes. Mutations are found throughout the protein (Fig. 136-5) and most commonly lead to diminished cell surface expression, although some impair protein activity.

MCP and factor H bind C3b and facilitate its cleavage on the cell membrane by factor I. Factor I mutations are observed in approximately 12% of aHUS patients, most commonly resulting in decreased protein expression, although some mutations cause decreased catalytic activity, which is mediated through the factor I light chain.

Activating mutations in factor B and C3 are observed in approximately 3% and 10% of aHUS patients, respectively. Mutations in factor B lead to enhanced formation or greater stability of the C3 convertase on cell surfaces. Mutations in C3 may result in enhanced resistance to regulation. Mutations in thrombomodulin, which block the ability to accelerate factor I–mediated inactivation of C3b, have also been observed in several patients.

The basis for incomplete penetrance of aHUS is not understood. Identified precipitating factors include infection, pregnancy, and additional single nucleotide genetic polymorphisms and haplotypes in complement regulatory genes. Approximately 20% of patients harbor more than one mutation in complement regulatory genes. The cause of aHUS in the 30% of patients with no identified complement protein mutations remains uncertain.

Clinical Manifestations of Thrombotic Microangiopathies

By definition, microangiopathic hemolytic anemia and thrombocytopenia are cardinal signs/features of all TMA syndromes. However, some syndromes display relatively specific features that may help in their identification.

TTP

The classic pentad of signs and symptoms that compose the TTP syndrome include microangiopathic hemolytic anemia (MAHA), thrombocytopenia, neurologic impairment, fever, and renal dysfunction. In early studies, approximately 75% of patients presented with a triad of MAHA, neurologic impairment, and thrombocytopenic purpura. However, earlier recognition and the established efficacy of plasma exchange have led to the appreciation that MAHA and thrombocytopenia, in the absence of an obvious precipitating condition, are sufficient to make a presumptive diagnosis of TTP. Indeed, the evolution of this diagnostic approach has led to a significant increase in the use of plasma exchange, and it is likely that TTP is now as frequently overdiagnosed as underdiagnosed.

Approximately 10% to 40% of patients with TTP recall an upper respiratory tract infection or flu-like syndrome in the weeks preceding diagnosis. Patients may present with malaise, fatigue, fever, or other nonspecific symptoms of days to weeks duration unresponsive to antibiotics or symptomatic management. The diagnosis of TTP may be overlooked until these prodromal symptoms become unrelenting or neurologic dysfunction develops. Neurologic symptoms ranging from headache and confusion to somnolence, seizures, aphasia, or coma often dominate the clinical picture in TTP and may fluctuate in severity, a characteristic attributed to the repetitive formation and dissolution of thrombi in the cerebral microvasculature. Other less common symptoms are abdominal pain and respiratory distress. Thrombocytopenia may be severe, with platelet counts below 20,000/μL, and mucocutaneous bleeding is common.

Stx-HUS

Stx-HUS occurs most commonly after *E. coli* O157:H7–induced gastroenteritis, with rare cases reported after infection of the urinary tract or skin, or infection with non-*E. coli* organisms. The disease begins with the sudden onset of abdominal pain and watery diarrhea, on average 3.7 days (range, 2-12 days) after toxin exposure. Abdominal pain may be severe and precede the onset of diarrhea. This presentation, particularly in the absence of fever, may be difficult to differentiate from inflammatory bowel disease, appendicitis, ischemic colitis, or intussusception. Bloody diarrhea generally ensues on the second day, accompanied in some cases by nausea and vomiting, though up to one-third of patients do not report blood in the stool. Fever is typically absent or mild. Colonoscopy reveals edematous colonic mucosa, with occasional ulceration and pseudomembrane formation. Thumbprinting in the distal ascending and proximal transverse colon, suggesting ischemic colitis, may be seen on barium enema and is attributed to exotoxin-induced thrombi in the microvasculature of the bowel wall.

E. coli–associated hemorrhagic gastroenteritis is complicated by HUS in 8% to 18% of sporadic cases, and over 20% in certain epidemic outbreaks. Thus the disease should be suspected in a patient who presents with characteristic clinical manifestations after an episode of bloody diarrhea, although the prototypic history of a preceding hemorrhagic gastroenteritis may be absent in up to 30%

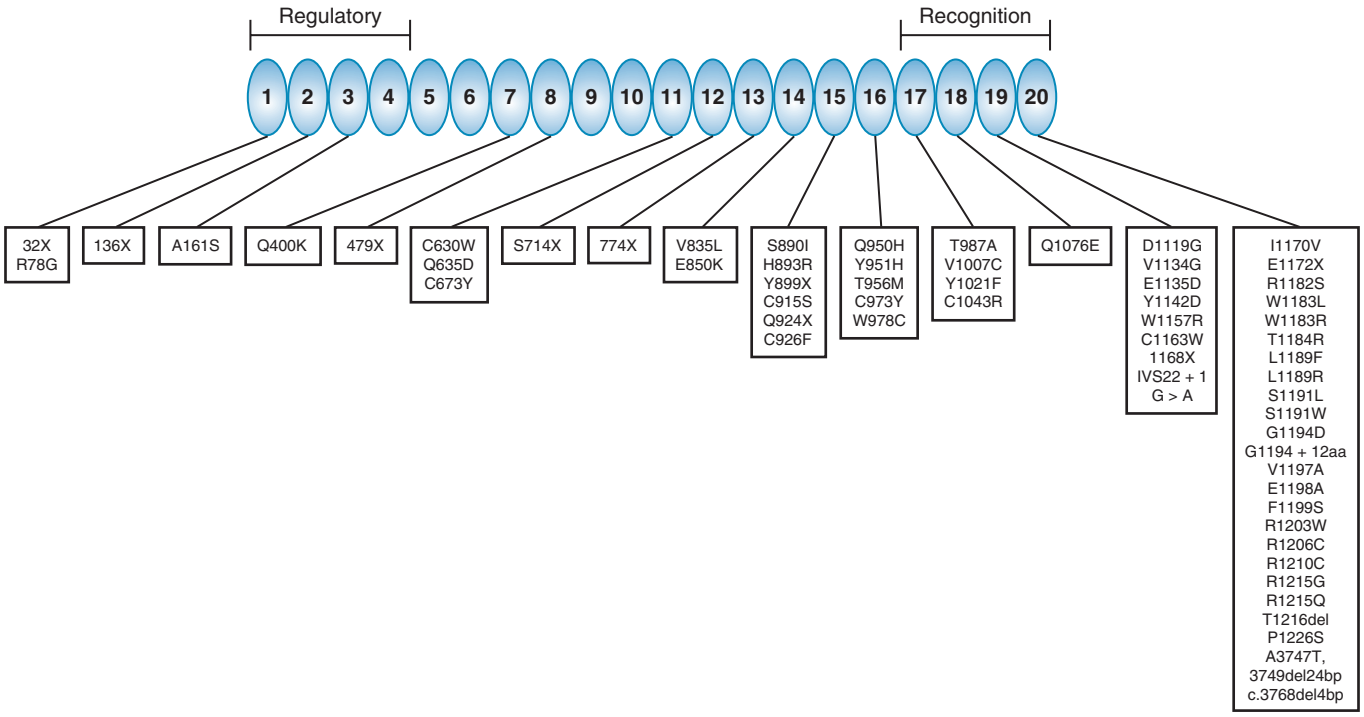

Figure 136-4 FACTOR H CONSISTS OF 20 SCRs, WITH THE MAJORITY OF aHUS MUTATIONS IN SCRs 19 AND 20. The N-terminal SCRs form the regulatory domain, and the C-terminal SCRs form the recognition domain. The sites of mutations reported in aHUS are shown. *(Reproduced from Kavanagh D, Goodship THJ: Atypical hemolytic uremic syndrome, genetic basis, and clinical manifestations.* Hematology Am Soc Hematol Educ Program *2011:15, 2011, with permission.)*

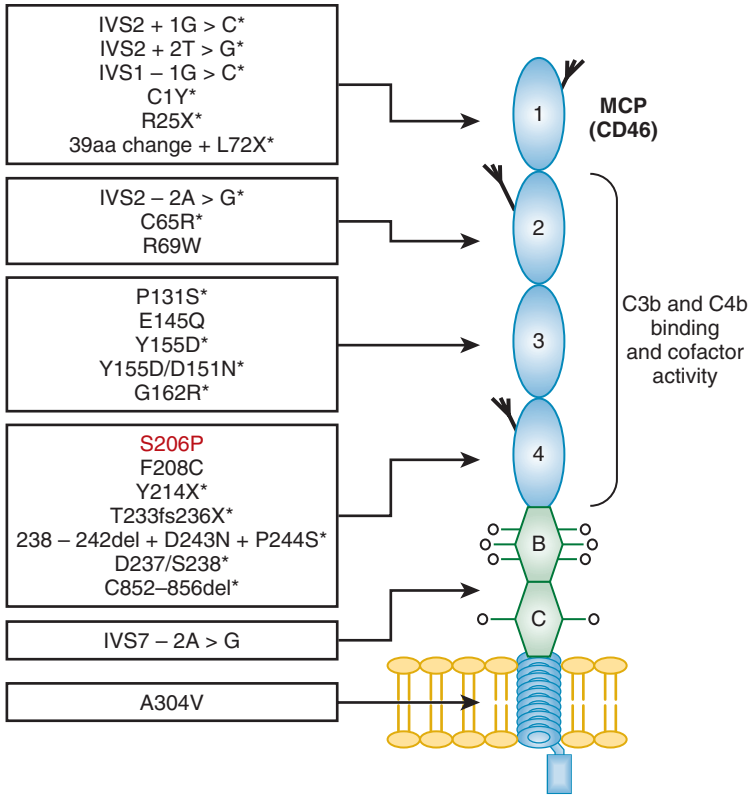

Figure 136-5 SCHEMATIC DIAGRAM OF THE STRUCTURE OF MCP AND DEPICTION OF THE INITIAL 24 MUTATIONS ASSOCIATED WITH aHUS. MCP is a 65-kDa type 1 transmembrane glycoprotein. Beginning at the N-terminus, it consists of four 60 amino acid complement control repeats (also called *short consensus repeats* and occasionally referred to as "Sushi domains"). Modules 1, 2, and 4 each contain one N-glycosylation site. Next is an alternatively spliced region, rich in serines, threonines, and prolines that are sites for O-glycosylation. This is followed by a juxtamembranous sequence of 12 amino acids (encoded by a separate exon) of unknown function, a transmembrane hydrophobic domain, a charged intracellular anchor, and the alternatively spliced cytoplasmic tail (tail 1 or 2). The MCP-BC isoform is shown. Mutations associated with aHUS are primarily clustered in the four extracellular modules. Mutations associated with reduced expression levels are marked by an asterisk. *(From Richards A, Kavanagh D, Atkinson JP: Inherited complement regulatory protein deficiency predisposes to human disease in acute injury and chronic inflammatory states the examples of vascular damage in atypical hemolytic uremic syndrome and debris accumulation in age-related macular degeneration.* Adv Immunol *96:141, 2007, with permission.)*

of cases. Young children and older adults are at greatest risk, perhaps in part because of slower clearance of the organism from the gastrointestinal tract. HUS typically develops 7 days (range, 5-13 days) after the onset of diarrhea. Patients often present with oliguria or other evidence of renal impairment; 50% of patients require dialysis, at least temporarily. The severity of MAHA varies considerably, but many affected individuals require red cell transfusions. Thrombocytopenia is common, with a median platelet count of 30,000/μL in one study, but may be mild or absent in up to 30% of cases at presentation. Up to 25% of patients develop neurologic manifestations, which may include irritability and somnolence and less commonly, confusion, paresis, and seizures.

Isolation of patient with Stx-HUS should be considered, because shedding of the pathogenic bacterium may continue for prolonged periods after cessation of diarrhea.

Atypical HUS

Like TTP, aHUS may present with a prodrome suggestive of an upper respiratory tract infection or nonspecific symptoms of malaise and fatigue, but severe abdominal pain and bloody diarrhea are absent. Neurologic manifestations are typically less common and severe than in TTP and are less likely to dominate the course. MAHA is universal, and the reticulocyte count and LDH concentration are elevated, but severe thrombocytopenia is less common than in TTP. aHUS does not display the seasonal variability characteristic of Stx-HUS. Renal involvement is more severe than in TTP, with up to 60% of patients requiring dialysis.

aHUS typically runs a chronic relapsing course, often complicated by hypertension and renal insufficiency. This disorder may resemble TMAs associated with pregnancy, cancer, and chemotherapy, which have similar clinical presentations, but different natural histories. Moreover, exacerbations are often preceded by infection, pregnancy, or other seemingly incidental events. Penetrance is approximately 50% in families with heterozygous mutations in complement regulatory proteins; thus aHUS may occur in siblings with identical genetic abnormalities at different times, or not at all. The prognosis of patients with factor H or factor I deficiency is poor, with a rate of recurrence and progression to end-stage renal disease or death of 70% in the former, whereas MCP deficiency carries a better prognosis. Aggressive treatment with plasma exchange or plasma infusions of 15 to 20 mL/kg weekly or biweekly may slow the progression of renal failure in some patients. However, there is limited evidence that plasma therapy or immunosuppression affects the clinical course.

Affected patients have a high risk for recurrence after renal allografting, and HUS occasionally presents in related donors after surgery. Since factor H is a soluble blood protein, factor H deficiency or dysfunction is not corrected by renal allografting, and HUS often recurs in the transplanted kidney, especially those from related donors.

Laboratory Manifestations of Thrombotic Microangiopathies

With improved understanding of the pathogenesis of TMA, laboratory evaluation is becoming increasingly important. Though the initial diagnosis of these disorders remains based on clinical features, the CBC, and peripheral blood film, faster turnaround times for laboratory studies, such as determination of ADAMTS13 levels, may improve diagnosis and management.

TTP

The presence of schistocytes on the peripheral blood smear is a characteristic laboratory finding of TTP (Fig. 136-6), although these may not be apparent in rare patients at disease onset. The markedly elevated levels of plasma lactate dehydrogenase (LDH) typically seen in patients with TTP reflect both hemolysis and tissue ischemia. Nucleated red blood cells are present in many patients, and their number may be disproportionately increased in comparison to the degree of reticulocytosis. With rare exceptions, the direct antiglobulin test is negative. The prothrombin time, partial thromboplastin time, and fibrinogen levels are usually normal or only mildly perturbed; mild elevations in fibrinogen degradation products occur in 50% of patients though more sensitive assays, such as those for prothrombin fragment 1+2. Thrombin-antithrombin and plasmin-antiplasmin complexes often demonstrate low-grade activation of coagulation and fibrinolytic pathways. Evidence of renal involvement may include hematuria, proteinuria, granular or red cell casts, and mild azotemia, though anuria and renal failure are uncommon presenting features. A severe deficiency (<5%) of ADAMTS13 in the appropriate clinical setting is considered diagnostic of TTP, though TTP is not excluded by a normal or only moderately decreased level (see box on ADAMTS13 in the Management of TTP).

The prototypic vascular lesions of TTP are characterized by platelet-rich thrombi within or beneath damaged endothelium. Involved microvascular endothelial cells are swollen and in some cases detached. The subendothelium contains hyaline material that is relatively poor

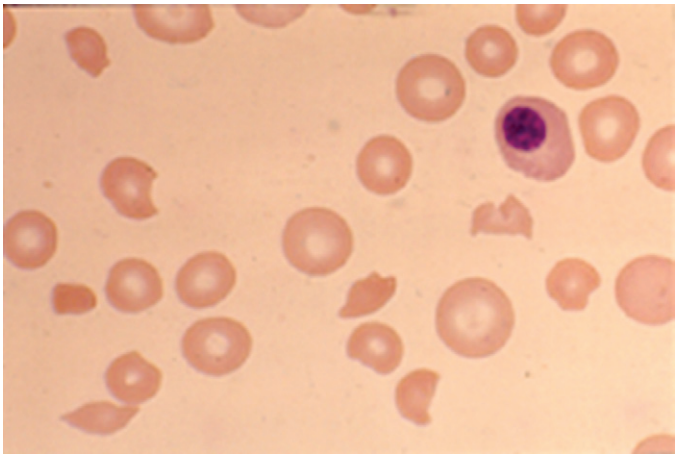

Figure 136-6 THIS PERIPHERAL BLOOD FILM WAS OBTAINED FROM A 28-YEAR-OLD WOMAN WHO PRESENTED WITH FEVER, EPISTAXIS, AND ALTERED MENTAL STATUS. Note the absence of platelets and the presence of a nucleated erythrocyte and schistocytes *(arrows),* consistent with a microangiopathic process.

ADAMTS13 in the Management of TTP

A role for vWF in the pathogenesis of TTP was suspected in the early 1980s, when reports describing the presence of ultralarge vWF multimers in the plasma of affected patients first appeared. This finding led to the hypothesis that TTP might result from deficiency of a protease responsible for vWF cleavage, and almost 20 years later, the vWF cleaving protease was isolated and found to be deficient in most patients with TTP. This protease was subsequently cloned, found to be a member of the ADAMTS metalloprotease family, and denoted ADAMTS13. This advance raised expectations that a simple and accurate diagnostic test would soon be available for the diagnosis of TTP. However, the utility of ADAMTS13 testing remains undefined, due in part to issues such as a lack of assay standardization and the use of different inclusion criteria in studies that have assessed the relevance of ADAMTS13 measurements. Despite these obstacles, areas where this assay may be useful have begun to emerge. First, for patients with thrombotic microangiopathy, severe ADAMTS13 deficiency is specific for idiopathic TTP but may also occur, albeit uncommonly, in other disorders such as sepsis-induced DIC or severe liver failure. Thus although severe ADAMTS13 deficiency is consistent with TTP, it is not diagnostic in the absence of other clinical information. Moreover, normal or moderately reduced ADAMTS13 levels (20% to 40%) do not exclude the diagnosis of TTP. Second, severe ADAMTS13 deficiency at presentation correlates with an increased risk for relapsing TTP, approximately 30% during 2 years of follow-up. Conversely, patients without severe ADAMTS13 deficiency at presentation rarely relapse. Third, persistence or recurrence of severe ADAMTS13 deficiency further increases the risk for relapse, suggesting that monitoring ADAMTS13 activity may prove useful to select patients for additional intensive therapy. However, because these relationships are based on relatively small case series, they require validation in larger, prospective studies.

in fibrin but consists largely of vWF and platelet remnants. In contrast, the lesions of HUS are rich in fibrin and contain comparatively little vWF. Involved vessel walls characteristically display a paucity of mononuclear leukocytes; fibrinoid necrosis, aneurysm formation, and other evidence of vasculitis are absent. Medium- and large-sized arteries show less extensive involvement, and the venous system is typically spared. The most commonly affected organs include the brain, pancreas, heart, and adrenal glands. Involvement of other sites such as the kidney, spleen, gingiva, bone marrow, and skin (Fig. 136-7) may occur as well. A characteristic pathologic lesion involving adjacent areas of vascular dilatation and constriction accompanied by segmental hyaline changes may occur in the placenta.

Stx-HUS

Like TTP, Stx-HUS is characterized by microangiopathic hemolytic anemia and thrombocytopenia. A preceding history of gastroenteritis is common. Thrombocytopenia tends to be less severe than in TTP, and renal disease is the major clinical manifestation.

Renal biopsy, although rarely required for diagnosis in endemic areas, highlights the importance of endothelial damage. Involved glomeruli show widening of the subendothelial space, which is filled with cellular debris and fibrin**.** Glomerular capillary endothelial cells are swollen and occasionally detached, leading to obliteration of the capillary lumens.

Though clinical features are often sufficient for the diagnosis of Stx-HUS, bacteriologic confirmation should be sought through stool cultures, testing for Stx toxin, and acute and convalescent serologies. Stool should be tested as soon as possible after the onset of diarrhea. The recovery rate for STEC appears to be at least 90% during the first 6 days but less than 33% thereafter. *E. coli* O157:H7 ferments sorbitol slowly, appearing as colorless overnight colonies on sorbitol-MacConkey agar; sorbitol-negative cultures may be characterized further using commercially available O157:H7-specific antisera. Methods to detect Stx toxins or their structural genes improve diagnostic sensitivity and also can detect the rare sorbitol-fermenting O157:H7, as well as non-O157:H7 STEC. However, the risk for developing HUS associated with non-O157:H7 STEC varies and is often relatively low.

Antibody titers against *E. coli* O157:H7 antigens and Stx rise after infection, persist for 8 to 12 weeks, and may be useful to confirm STEC infection in selected cases; however, they are not widely available.

Atypical HUS

aHUS is characterized by microangiopathic hemolytic anemia and thrombocytopenia. Compared with TTP, thrombocytopenia and anemia may be less severe and renal insufficiency more prominent. Before the realization that complement activation plays a prominent role in most cases of aHUS, this disorder was primarily diagnosed clinically. However, recent guidelines have emphasized the importance of laboratory studies to diagnose aHUS and distinguish it from other thrombotic microangiopathies.

Diagnosis of aHUS requires several criteria, including: (1) the absence of other diseases associated with TMA, (2) no criteria for

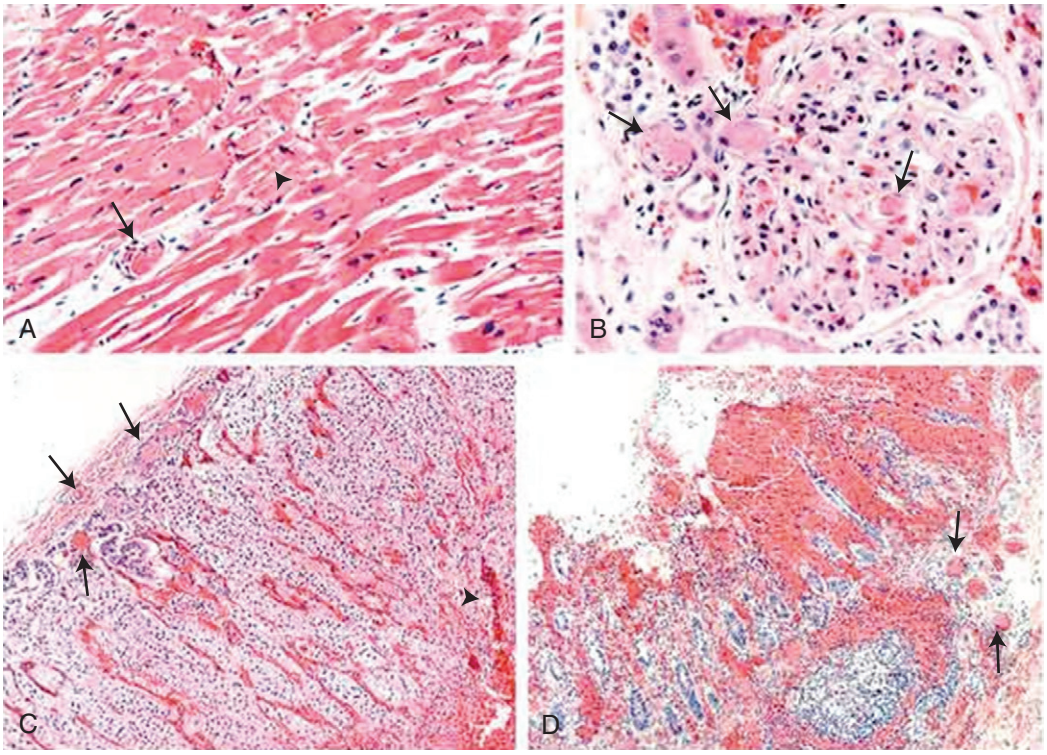

Figure 136-7 TISSUE SPECIMENS OBTAINED AT AUTOPSY FROM A PATIENT WITH ABNORMALITIES CHARACTERISTIC OF THROMBOTIC THROMBOCYTOPENIC PURPURA. A specimen from the heart **(A)** shows multiple intramyocardial microthrombi (*arrow*), hemorrhage, and early ischemic changes, with scattered foci of contraction-band necrosis (*arrowhead*). A specimen from the kidney **(B)** shows characteristic microthrombi in an afferent arteriole, the glomerular hilum, and glomerular capillaries (*arrows*), with vascular congestion and parenchymal hemorrhage in the surrounding interstitium. A tissue specimen from the adrenal gland **(C)** shows characteristic subcapsular microthrombi (*arrows*), with congestion of cortical arterioles and medullary parenchymal hemorrhage *(arrowhead).* A specimen from the cecum **(D)** shows submucosal microthrombi *(arrows)* and hemorrhagic mucosal ulceration and necrosis. Microthrombi were also present in the pancreas, thyroid gland, and other organs. *(Reproduced from George, JN: Thrombotic thrombocytopenic purpura.* N Engl J Med *354:1927, 2006, with permission. Photographs and interpretation by Patrick Stangeby.)*

Stx-HUS (negative stool culture and Stx assays), and (3) no criteria for TTP (ADAMTS13 >10%). In addition, the complement system should be studied, since abnormalities of complement regulation are involved in at least 70% of cases. Real-time measurement of complement and complement inhibitory proteins are available in a few clinical laboratories. Investigations should include measurement of C3 and C4, as well as factors H, I, and B. MCP (CD46) can and should be measured on circulating mononuclear cells, and plasma should be screened for anti–factor H antibodies. Finally, mutation analyses of the nine genes that have been implicated in the pathogenesis of aHUS (CFH, CFI, C3, MCP, CFB, THBD, deletions of CFH1 and CFH3, or CFH1 and CFH4) should be pursued. The frequency of low C3 levels varies depending on the type of gene mutation present; C3 is reduced in essentially all patients with CFB mutations but in only 30% to 50% of patients with CFH mutations. Plasma concentrations of complement and complement inhibitory proteins in various subgroups of aHUS classified by mutation are shown in Table 136-2.

Differential Diagnosis

The differential diagnosis of MAHA and thrombocytopenia is extensive. Vascular damage secondary to systemic lupus erythematosus, scleroderma, septic or tumor emboli, immune complex-mediated vasculitis (e.g., infective endocarditis), malignant hypertension, cryoglobulinemia, or infection with rickettsial or, more rarely, hemorrhage-inducing viral organisms, may all mimic thrombotic microangiopathy. TMA may also be superimposed on preexisting immune vascular disorders such as systemic lupus erythematosus or the antiphospholipid syndrome (see Chapter 143). Occasional patients with disseminated intravascular coagulation secondary to malignancy or sepsis present with microangiopathy of sufficient severity to be confused with primary TMA (see Chapter 141). In the setting of renal transplantation, a biopsy may be required to distinguish TMA from allograft rejection or recurrence of a preexisting renal vascular disorder. Occasional patients present with acute pancreatitis, acute respiratory distress syndrome, memory and personality changes, or other poorly defined neurologic symptoms that themselves have a broad differential diagnosis.

TMA may also occur in other well-defined clinical settings. Some of these are considered part the category of "nonidiopathic TTP" because of their clinical associations, though the pathogenesis of these disorders is generally not well understood and their responses to various therapeutic interventions are not well defined.

Posttransplantation and Cyclosporine

Thrombotic microangiopathies occur most commonly in three transplant-related settings: (1) in association with the use of cyclosporine A (CyA), (2) as recurrent disease after transplantation for a TMA-related disorder, and (3) after hematopoietic stem cell transplantation.

Cyclosporine A

Cyclosporine A is a common cause of drug-induced thrombotic microangiopathy. CyA is cytotoxic to cultured endothelial cells at concentrations similar to the peak plasma levels and tissue concentrations achieved in vivo. Plasma levels of vWF and endothelin-1 are elevated during episodes of nephrotoxicity, consistent with endothelial cell injury. CyA also enhances platelet aggregation and thromboxane release.

TMA occurs in 1% to 5% of renal transplant recipients, as well as in occasional solid organ recipients treated with CyA or tacrolimus. CyA-induced TMA typically develops insidiously with progressive, otherwise unexplained renal insufficiency. MAHA or thrombocytopenia develops in only half these patients and is usually mild. The appearance of the glomerular capillary and arteriolar thrombotic lesions is similar to that in primary cases of TMA. The distinction of CyA-induced TMA from acute tubular necrosis or rejection can often be made only by biopsy, and an unequivocal distinction cannot be established in every case. Broad alloantibody reactivity and coinfection with cytomegalovirus may predispose to CyA-associated TMA.

CyA-induced TMA often responds to a reduction of the dose or temporary discontinuation of CyA. The prognosis is generally good, although some patients develop permanent renal failure. In many patients, CyA can be reintroduced at a lower dose; in others, tacrolimus has been substituted successfully, although the latter may also precipitate thrombotic microangiopathy. The utility of plasma exchange is uncertain.

Renal Transplantation

Approximately 50% of patients with aHUS develop end-stage renal insufficiency and become candidates for renal transplantation. Thrombotic microangiopathy may recur in up to 50% of transplanted kidneys, and 80% to 90% of these grafts will be lost. Recent studies from an Italian registry demonstrated that the risk for aHUS recurrence varies as a function of the complement abnormalities that originally contributed to aHUS. For example, the risk for

Table 136-2 Plasma Concentration of C3, C4, CFH, CFI, and CFB and Expression of Membrane Cofactor Protein in the Various Subgroups of Atypical Hemolytic Uremic Syndrome

	Protein Level or Expression					
	C4	**C3**	**CFH**	**CFI**	**CFB**	**MCP**
CFH mutation	N	Normal (decreased)	Normal (decreased)	Normal	Normal (decreased)	Normal
CFI mutation	N	Normal (decreased)	Normal	Normal (decreased)	Normal (decreased)	Normal
MCP mutation	N	Normal (decreased)	Normal	Normal	Normal	Decreased (normal)
CFB mutation	N	Decreased	Normal	Normal	Normal (decreased)	Normal
C3 mutation	N	Decreased	Normal	Normal	Normal (decreased)	Normal
THBD mutation	N	Normal or decreased	ND	ND	ND	Normal
Anti-CFH Ab	N	Decreased (normal)	Normal (decreased)	Normal	Normal (decreased)	Normal

Data from Loirat C, Frémeaux-Bacchi V: Atypical hemolytic uremic syndrome. *Orphanet J Rare Diseases* 6:60, 2011.
Note: Very low C3 levels are observed in patients with homozygous CFH mutation (complete CFH deficiency) or compound heterozygous CFH mutation, and in patients with CFB or C3 gain-of-function mutations. In most of the other patients, C3 concentration is mildly decreased or normal. Undetectable CFH concentrations are observed only in patients with homozygous CFH mutation. Decreased CFH concentration can be observed in patients with heterozygous type 1 *CFH* mutation, and during flares of anti-CFH antibodies-HUS. Decreased C4 plasma levels have been reported in zero to a few patients of the various subgroups.
"Normal" and "Decreased" without parentheses mean most frequently, normal or decreased. "Normal" and "Decreased" within parentheses mean possible, but not frequent. "Normal or decreased" without parentheses means that normal or decreased is equally frequent.
Ab, antibodies; *CFB*, factor B; *CFH*, Factor H; *CFI*, factor I; *ND*, not documented; *THBD*, thrombomodulin.

posttransplant HUS is 75% to 90% in patients with CFH, 45% to 80% in patients with CFI, and 40% to 70% in patients with C3 mutations, respectively. In contrast, the risk for recurrence in individuals with MCP mutations is 0% to 20%, since the transplanted organ provides wild-type MCP. The type of complement mutation is also associated with the timing of recurrence following transplantation. Thus for the hematologist evaluating posttransplant TMA, a careful, multigenerational history must be taken to exclude the possibility of familial TMA, and the possibility of an inherited mutation in complement regulatory genes must be considered.

Hematopoietic Stem Cell Transplantation

TMA occurs in approximately 6% of patients who undergo allogeneic marrow transplantation; the incidence is estimated to be 0.1% to 1% after autologous marrow or stem cell transplantation. Though guidelines have been developed, diagnosis is difficult since schistocytes and thrombocytopenia are common after bone marrow transplantation, and the differential diagnosis of fever, renal failure, and neurologic complications is extensive. The clinical manifestations typically begin months after transplantation. The pathophysiology is assumed to reflect systemic endothelial cell injury from a variety of causes. vWF protease activity may fall after transplantation, but severe deficiency as occurs in TTP is uncommon. Risk factors include use of an unrelated or mismatched donor, total body irradiation as part of the pretransplant conditioning regime, CyA or tacrolimus posttransplant, systemic cytomegalovirus or other infection, older age, female gender, and graft-versus-host disease (GVHD). Systemic microangiopathy is rare, but an intestinal biopsy may be needed to distinguish thrombotic microangiopathy from graft-versus-host disease in patients with refractory diarrhea.

Withdrawal or substitution of another immunosuppressive for CyA, if possible, should be considered, although at the risk for worsening of the underlying GVHD. Alternative causes should be sought, and aggressive treatment of infection and GVHD should be employed in all but the most overt cases. It is difficult to determine the prognosis because of variable inclusion criteria. Although patients may appear to show an initial response to plasma therapy, the effectiveness of plasma exchange has not been established and mortality exceeds 50%, often due to complications of GVHD or opportunistic infection. Defibrotide has been used with reported success in a few cases, and there have been anecdotal successes using rituximab or anti-CD25 antibodies.

Cancer and Chemotherapy-Associated Thrombotic Microangiopathy

TMA may terminate the course of some patients with disseminated malignant neoplasms and large tumor burdens, most commonly adenocarcinoma of the gastrointestinal tract, breast, or lung. Patients generally present with an abrupt onset of moderate to severe MAHA and thrombocytopenia. Renal insufficiency and neurologic dysfunction occur less commonly than in idiopathic or chemotherapy-induced thrombotic microangiopathy and may result from concurrent metabolic disturbances, central nervous system metastases, stroke, or hemorrhage.

The pathogenesis of cancer-associated thrombotic microangiopathy remains poorly understood. Laboratory evidence of DIC is found in 25% to 80% of patients based on findings of elevated fibrin-split products or more sensitive measures of fibrinogen turnover. However, the observation that TMA occurs in only 5% of patients with disseminated malignancy and DIC suggests the involvement of additional factors, such as microvascular occlusion, intimal proliferation induced by tumor emboli within the pulmonary vasculature, or formation of an incompletely endothelialized tumor vasculature that predisposes to platelet adhesion. Severe deficiency of ADAMTS13 is not typical. Survival is generally measured in weeks. The only effective therapy is reduction of the tumor burden, a goal often not attainable. A role for plasma exchange has not been established.

Specific cancer chemotherapeutic agents have also been implicated in the development of TMA. Patients are often receiving therapy for adenocarcinoma at the time TMA develops, making attribution to the neoplasm versus its therapy difficult to determine. However, unlike cancer-associated TMA, most patients with chemotherapy-associated TMA do not have a large tumor burden, and some may be in remission. Mitomycin-C, gemcitabine, cis-platinum, bleomycin, docetaxel, 5-fluourouracil, deoxycoformycin, carboplatin, and interferon-α, either alone or in combination, have been implicated.

Patients with chemotherapy-associated TMA generally present with moderate to severe MAHA, thrombocytopenia, and renal insufficiency (median creatinine value of 4.2 mg/dL). Approximately 15% to 20% of patients develop neurologic dysfunction. A unique feature in some series is noncardiogenic pulmonary edema in over 50% of patients. Pulmonary function may deteriorate rapidly after red blood cell or platelet transfusion, which should be used with caution.

Chemotherapy-associated TMA is presumed to result from direct toxicity to the endothelium. Mitomycin inhibits the production of prostacyclin by umbilical vein endothelium, and infusion of mitomycin-C into the rat kidney induces histologic changes similar to those of chemotherapy-induced TMA. ADAMST13 levels are not severely reduced. Fewer than 20% of affected patients appear to respond to plasma exchange and/or corticosteroids, and more than 50% die within 2 months.

Streptococcus Pneumonia and Disorders of Cobalamin Metabolism

Infection with *S. pneumonia* may lead to desialylation of the glycocalyx of cells that express the Thomsen-Freidenreich (T-F) antigen. A naturally occurring, cold reactive IgM may recognize the exposed antigen, leading to red cell agglutination in vitro. This disorder generally occurs in children less than 2 years of age and is associated with significant mortality. The pathogenesis is not well defined but may involve interactions among the IgM, red cells, platelets, and endothelium. Affected individuals have a positive antiglobulin test.

An autosomal recessive thrombotic microangiopathy associated with disordered cobalamin-C metabolism can occur in individuals during the first weeks to months of life. Deficiency of cobalamin-C may result in markedly elevated levels of homocysteine and methylmalonic acid, which may be responsible for vascular injury. Though many individuals develop a fulminant course leading to death, occasional patients display a more chronic form of the disease later in childhood.

Miscellaneous Drug-Associated Thrombotic Microangiopathy

TMA has been associated uncommonly with more than 50 other drugs, including penicillins, ciprofloxacin, clarithromycin, histamine H_2-receptor antagonists, the Norplant contraceptive, thienopyridines, and others. The mechanisms by which these agents induce TMA may differ, as may the natural history and response to therapy. Whereas mitomycin C, gemcitabine, and CyA appear to induce TMA in a cumulative dose-dependent manner, quinidine and thienopyridines (ticlopidine and clopidogrel) induce thrombotic microangiopathy through either idiosyncratic, immune-mediated mechanisms or acute endothelial toxicity (see Chapter 133).

An association of quinine with thrombotic microangiopathy was first reported by Gottschall and colleagues, who described the course of three patients with a syndrome resembling idiopathic HUS. Patients generally present with severe MAHA, platelet counts below 50,000/μL and renal insufficiency, usually requiring dialysis. Neurologic dysfunction occurs in a minority of patients, it but can be severe; granulocytopenia and lymphopenia have been reported. In earlier reports, the prognosis was favorable once quinine was withdrawn and plasma exchange instituted. However, in another series, 17 of 225 patients with HUS had quinine-associated thrombotic

microangiopathy, 4 of whom died, and 7 survivors were left with chronic renal failure. Although this disorder occurs most commonly after the ingestion of quinine tablets, cases have been reported after exposure to quinine in beverages such as tonic water, and the syndrome may recur rapidly upon reexposure. The pathogenesis may involve idiosyncratic, quinine-dependent antibodies reactive with platelet glycoproteins IIb/IIIa and Ib/IX and related antigens on endothelial cells and neutrophils that promote neutrophil aggregation and binding to endothelial cells in a drug-dependent manner.

The thienopyridines are another common cause of drug-induced TTP. TTP occurs in a higher percentage of patients exposed to ticlopidine, with an incidence ranging from 1 : 600 to 1 : 4814 patient exposures in contrast to an estimated incidence of 4 per 1,000,000 to 1 per 8500 to 26,000 exposures in patients taking clopidogrel. No cases of clopidogrel-associated TTP were encountered in the CAPRIE and CURE studies, each of which enrolled more than 6200 patients. Despite the low incidence, the frequency with which clopidogrel is prescribed renders it the most commonly reported drug associated with TTP in the FDA's MedWatch database, accounting for more than 30% of all cases. The pathogenesis and natural history of TTP associated with ticlopidine and clopidogrel differ. Reductions in ADAMTS13 activity below 15% occur in 85% of patients with ticlopidine-associated TTP but in only 15% of patients with clopidogrel-associated TTP. Reduced ADAMTS13 reflects the development of anti-ADAMTS13 antibodies. TTP generally develops within 2 to 12 weeks of starting ticlopidine and responds relatively quickly to plasma exchange. Spontaneous relapses may occur. In contrast, 90% of patients exposed to clopidogrel but only 10% of patients exposed to ticlopidine develop a syndrome characterized primarily by MAHA and renal insufficiency, without severe thrombocytopenia; these individuals have normal levels of ADAMTS13, usually develop disease within the first 2 weeks of exposure, and may require several weeks of plasma exchange to achieve remission. Whether plasma exchange actually improves the clinical outcome is uncertain. Spontaneous relapses are uncommon.

Finally, the increasing use of anti-VEGF antibodies and other VEGF inhibitors has revealed a critical dependence of podocytes and glomerular endothelial cells on VEGF. Toxicity of these agents may include a thrombotic microangiopathy localized primarily to the kidney and manifested mainly by hypertension and proteinuria.

HIV-Associated Thrombotic Microangiopathy

An association between HIV infection and TMA has been recognized since 1984. Before the introduction of highly active antiretroviral therapy in the mid-1990s, TMA occurred in up to 7% of patients hospitalized with HIV infection. Conversely, the incidence of HIV infection in patients with TMA varied from 15% to 50% in endemic areas. Diagnosis was often difficult because fever, anemia, thrombocytopenia, nephropathy, neurologic dysfunction, and elevated LDH levels secondary to lymphoma, drug reactions, or pulmonary infection with *Pneumocystis carinii* occurred commonly in this population. In contrast, TMA is rare in HIV patients who are treated effectively with antiretroviral therapy. TMA that does occur in advanced or untreated HIV patients often responds quickly to the initiation of antiretroviral therapy and can relapse if therapy is discontinued.

In some patients with HIV infection, the associated immune dysfunction may predispose to the formation of autoantibodies against ADAMTS13, with severe ADAMTS13 deficiency and the development of TTP, despite adequate treatment for HIV. These patients may respond to plasma exchange.

PREGNANCY-ASSOCIATED THROMBOTIC MICROANGIOPATHY

The differential diagnosis of MAHA associated with gestation is complex. TMA may be difficult if not impossible to distinguish from other causes of MAHA unique to pregnancy, such as preeclampsia, acute fatty liver associated with DIC, and HELLP syndrome (which stands for hemolysis, elevated liver function tests, and low platelet counts). The severity of the renal and neurologic abnormalities and the time during gestation at which the signs and symptoms of TMA first appear may provide clues needed to prevent critical delays in therapy.

Approximately 10% of cases of idiopathic TTP occur in association with pregnancy. In one series, 40 of 45 cases of TTP in pregnancy were diagnosed antepartum, at a mean gestational age of 23.5 weeks. Additional studies have confirmed that TTP develops frequently in the second trimester, although some studies report more common occurrence in the third, or immediately postpartum. In the absence of appropriate therapy, maternal and fetal mortality approach 90%. There is no evidence that uterine evacuation leads to resolution. ADAMST13 levels fall progressively during pregnancy, but severe deficiency (<5%) is seen only in women with TTP. The prognosis of pregnancy-associated TTP has improved dramatically since the advent of plasma exchange, and continuing pregnancy does not impair response. Many patients carry to term successfully, although the overall risk for fetal loss remains significant.

Up to 20% of patients with chronic, relapsing TTP have recurrences during subsequent pregnancies, whereas recurrence occurs in almost all women with inherited ADAMTS13 deficiency. TTP during pregnancy carries an extremely high risk for fetal loss. Pregnancies in women with congenital ADAMTS13 deficiency have been carried to term successfully by treatment with prophylactic plasma infusions, sometimes combined with aspirin and low-molecular-weight heparin.

aHUS also occurs with increased frequency during pregnancy, and it is likely the underlying disorder previously referred to in various publications as *malignant nephrosclerosis, irreversible postpartum renal failure*, or *postpartum intravascular coagulation*. The disorder primarily affects primiparas who present with MAHA, thrombocytopenia, renal insufficiency and hypertension beginning with a mean time to onset of approximately 26 days after delivery in one series; this later onset may help to distinguish HUS from other causes of pregnancy-associated MAHA and thrombocytopenia, such as preeclampsia and HELLP, which occur late in gestation or soon after parturition. Recent studies have predictably noted a high incidence of complement regulatory protein mutations, particularly factor H, in patients with pregnancy-associated aHUS.

Prognosis

The prognosis for patients with thrombotic microangiopathies varies depending on the etiology and type of underlying genetic lesion, if any. Assuming timely diagnosis and effective therapy at initial presentation, the prognosis of primary TMAs is relatively favorable. For example, although older historic data suggest a response rate in TTP to plasma exchange of approximately 80%, a recent retrospective review of 134 episodes of TTP treated at Johns Hopkins Hospital found an all-cause mortality of only 4%. This apparent improvement in outcome may be generalized and reflects advances in supportive care as well as active therapies. Patients with acquired TTP continue to experience a significant relapse rate of 30% to 50%, though a recent report suggests that this may be reduced by therapy with rituximab during their initial treatment.

Though patients with congenital deficiency of ADAMTS13 may follow a chronic, relapsing course, relapses may be prevented by periodic plasma infusions. Insufficient numbers of patients have been followed to determine whether overall survival is reduced, although a natural history study identified individuals who survived into the seventh to eighth decades.

The outcomes of patients with Stx-HUS are generally favorable, although Stx-HUS remains the most common cause of acute renal failure in children and up to 60% of children require dialysis during the acute phase. However, Stx-HUS is usually self-limited and as a result of advances in supportive care, mortality has been reduced to

3% to 5%, with death usually due to severe involvement of the central nervous system, intestine, or myocardium. Renal insufficiency generally resolves within 2 to 3 weeks, although some patients have prolonged anuria, requiring several months before recovery. Despite a favorable short-term outcome, many children with Stx-HUS develop chronic renal insufficiency over time. In one report of 29 patients with "typical" childhood HUS followed for 15 to 28 years, 7 developed chronic renal failure and 12 developed hypertension, proteinuria, or reduced glomerular filtration rate, whereas only 10 showed no residual abnormalities. Thus 50% to 60% of patients have complete recovery with long-term preservation of renal function. Long-term outcome is worse in those presenting with prolonged anuria, an elevated leukocyte count, elevated levels of prothrombin fragment 1+2, tissue type plasminogen activator and PAI-1, and older age. Proteinuria persisting for more than 1 year after the initial episode of TMA is likewise associated with progressive renal disease. Given recent reports suggesting involvement of complement in the pathogenesis of Stx-HUS as well as aHUS, it is possible that the use of complement inhibitory drugs, such as eculizumab, might further reduce morbidity, though insufficient data are available to validate this hypothesis.

Atypical HUS has been historically associated with a poor prognosis, especially in older adults and those with severe renal dysfunction. The mortality rate approaches 25%, and 50% of surviving patients develop chronic renal insufficiency. However, as appreciation of the central role of complement in aHUS has expanded, prognostication based on genotype is becoming possible. For example, the observation that patients with CFH mutations may display a significant response rate to plasma exchange may explain the long-held but poorly understood clinical observation that a subfraction of aHUS patients do indeed respond to this intervention. Moreover, the recent approval of eculizumab for treatment of aHUS offers a new option (see the Therapy section, later in this chapter).

Pregnancy remains a significant risk factor for both TTP and aHUS, though gestation per se does not affect the response rates to therapy. The outcome of aHUS associated with pregnancy, in particular, has remained poor with mortality rates of as high as 50% and an additional 15% left with chronic renal insufficiency. Recent studies suggest that as in the nonpregnant setting, pregnancy-associated aHUS is closely tied to alternative complement pathway activation, and thus may respond to complement inhibitors.

Of the miscellaneous TMAs discussed in the Differential Diagnosis section earlier, prognosis depends on the underlying predisposition or etiology. Patients with quinine-induced TMA have a significant early mortality, though with appropriate supportive care and treatment of the acute episode, the disorder does not recur without reexposure to quinine. Likewise, TMA associated with CyA may respond to dose reduction or a change to another immunosuppressive agent and thus may be self-limited. Outcomes of patients who develop TMA in the setting of chemotherapy administration or advanced cancer are poor, because the TMA tends to be unrelenting and the comorbidity of the malignancy is significant. TMA associated with HSCT has a particularly poor prognosis, with mortality of 60% to 90%; this reflects an incomplete understanding of pathogenesis, limited response to plasma exchange, and only anecdotal responses to rituximab or anti-CD25 antibodies.

Therapy

Choosing the appropriate therapy depends on accurate diagnosis. However, the severity of thrombocytopenia, renal and neurologic involvement, and ADAMTS13 levels, if available, help to distinguish between TTP and aHUS, whereas the diagnosis of Stx-HUS is based on a compatible history and microbiologic testing. An ADAMTS13 level below 5% in the appropriate clinical context provides strong evidence for a diagnosis of TTP, although TTP should not be excluded in patients with characteristic/prototypic presentation whose levels of ADAMTS13 are not severely reduced.

TTP

The mortality rate of TTP exceeds 90% without therapy. Through the mid-1970s, splenectomy remained the only modality with more than an anecdotal response rate. Prognosis has been dramatically improved since the advent of plasma-based therapy, such that long-term survival now may exceed 90%.

Plasma Therapy

The beneficial effect of plasma therapy in TTP was first noted more than 3 decades ago. The results of a prospective trial reported in 1991 resolved the long-debated issue of the relative efficacy of plasma exchange versus infusion in favor of the former. At 6 months, complete remissions were seen in 78% of patients treated with exchange versus 31% of those treated with plasma infusion. This study did not resolve the question as to whether removal of a disease-inciting agent or replacement of a missing factor accounted for the superior response, particularly because patients in the exchange arm received a threefold greater volume of plasma. Indeed, a retrospective study demonstrated no significant difference in outcome in patients with acquired TTP who received equal volumes of plasma by exchange or infusion. However, the current model for the pathogenesis of acquired idiopathic TTP suggests that plasma exchange is superior because it both removes an IgG inhibitor of ADAMTS13 and replaces the deficient protein. In contrast, plasma infusion suffices for patients with genetic ADAMTS13 deficiency. Large volumes of plasma are more easily administered by exchange, and unless a genetic deficiency of ADAMTS13 has been documented, plasma infusion should be reserved for situations in which exchange is not immediately available. The recovery of ADAMTS13 levels may lag behind other indicators of clinical response, and the utility of monitoring ADAMTS13 levels during treatment has not been established (see box on ADAMTS13 in the Management of TTP).

Treatment is generally initiated with the goal of exchanging 1 to 1.5 plasma volumes (40 to 60 mL/kg) daily, although the optimal regimen has not been determined. The volume of exchange can be increased to 1.5 to 2 plasma volumes daily if the initial response is poor. Neurologic improvement occurs most rapidly, often within hours to days. The serum LDH level typically falls by 50% within 3 days in responders, and the platelet count begins to rise in a mean of 5 days, though normalization may take several weeks. Impaired renal function and disappearance of schistocytes are generally the last to improve.

Fresh frozen plasma (FFP) remains the most commonly used replacement product. There is no clear advantage to the use of cryopoor plasma (CPP), which is depleted of vWF. These findings are consistent with a recent study showing similar concentrations and stability of ADAMTS13 during storage at 1° C to 5° C in CPP and FFP. Pilot studies indicate that solvent-detergent treated plasma (which contains ADAMTS13 at concentrations approximately 20% below FFP) appears to be as efficacious as FFP with fewer allergic/urticarial reactions.

Daily plasma exchange should be continued until neurologic symptoms have resolved and both a normal serum LDH and platelet count have been achieved; many experts recommend an additional 2 to 3 days of plasma exchange thereafter. Approximately 85% to 90% of patients show a clinical and laboratory response to plasma exchange within 3 weeks, most often within 10 days (mean 15.8; range 3 to 36 days). However, 20% to 40% of patients will experience an exacerbation of disease within 30 days of plasma exchange discontinuation, whereas approximately 30% will relapse at later dates, usually within the first year. The decision to switch to CPP or to introduce another form of therapy is empiric but in general is not considered until the patient has received a minimum of 10 to 14 days of daily exchange with FFP. One study suggests that administration of rituximab early in the course of disease in conjunction with plasma exchange induces more rapid responses and reduces relapses. Little or no data support either abrupt discontinuation or "tapering" of plasma exchange after remission.

Complication rates associated with plasma therapy may approach 30%, mostly related to central venous catheter insertion or infection. Thrombosis has also been reported, and some, but not all reports suggest a higher incidence with the use of solvent-detergent—treated plasma, which contains less protein S, as a replacement fluid.

Plasma exchange is effective for patients with or without inhibitors, and clinical responses frequently occur despite persistence of both the inhibitor and severe ADAMTS13 deficiency, although patients with high titer inhibitors may respond more slowly and relapse more often. Both congenital and acquired ADAMTS13 deficiency are characterized by unpredictable periods of stability between relapses, which probably reflects a role of stress in exacerbating the disease by activating or damaging endothelium, increasing the release of unusually large vWF multimers, and triggering microvascular thrombosis.

Rituximab

Several reports support the efficacy the anti-CD20 antibody, rituximab, for decreasing the level of autoantibodies and restoring normal ADAMTS13 activity in TTP. Rituximab is being used with increasing frequency, primarily as salvage therapy for patients refractory to plasma exchange. Rituximab also has been used in individuals in remission who exhibit falling ADAMTS13 activity and recurring inhibitors, although the natural history of such patients is not well defined. In a prospective, nonrandomized study, patients with acute TTP who received rituximab within 3 days of admission, in addition to standard plasma exchange, experienced a more than fivefold lower relapse rate at a median of 18 months compared with historic controls. However, because of the lack of randomized trials of rituximab in primary or relapsed TTP, optimal application remains uncertain and the drug has not received FDA approval for this indication.

Corticosteroids

Corticosteroids are often used as part of initial therapy or for patients who fail to show a brisk response to plasma-based therapy. These drugs are of little benefit on their own, and retrospective studies do not provide compelling evidence that they improve the response to plasma exchange. However, the antiinflammatory and immunosuppressive effects of corticosteroids make them logical adjunctive therapy for autoimmune TTP, and most experts continue to use them in patients receiving plasma exchange.

Splenectomy

Before the introduction of plasma therapy, splenectomy was the first-line treatment for TTP and induced remission in up to 50% of patients. Currently, open or laparoscopic splenectomy is generally reserved for patients refractory to plasma exchange and rituximab. Splenectomy may reduce the frequency of relapses in patients with chronic relapsing TTP. Plasma exchange should be continued after splenectomy until the thrombotic microangiopathy remits.

Other Modalities

The response rate to aspirin, dipyridamole, sulfinpyrazone, or ticlopidine as single antiplatelet agents approximates 10%, essentially indistinguishable from the natural history. Antiplatelet agents have not been convincingly shown to increase the response to plasma exchange and may promote bleeding in the setting of severe thrombocytopenia and invasive procedures. The efficacy of intravenous immunoglobulin remains unproven. Anecdotal reports exist of favorable responses to vincristine, as well as other immunosuppressive therapies such as azathioprine, cyclophosphamide, cyclosporine, mycophenylate mofitil, and staphylococcal protein A immunoadsorption. There is evidence that CyA reduces the incidence of TTP relapse and decreases ADAMTS13 antibody levels with parallel increases ADAMTS13 activity.

Starting low-dose aspirin (81 mg daily) once the platelet count exceeds 50,000/μL has been recommended in the 2003 guidelines of the British Committee for Standards in Haematology. Folate supplementation and administration of the hepatitis B vaccine should be considered routine components of supportive care. The role of platelet transfusion in patients with TTP is uncertain (see box on Transfusion Therapy in Thrombotic Microangiopathy).

Stx-HUS

Early volume expansion, within the first 4 days of the onset of diarrhea, significantly reduces the incidence of progression to oliganuric HUS. However, no therapy has been shown to prevent HUS or reduce the severity of kidney injury once established. In randomized trials, neither plasma infusion nor exchange was of benefit in children or adults with Stx-associated HUS. Corticosteroids, heparin, urokinase, aspirin, and dipyridamole are ineffective. A silicon dioxide particle covalently linked to a trisaccharide, designed to bind toxin in the intestine and block systemic effects, did not show benefit. Antimotility agents and narcotics delay clearance of *E. coli* and toxin from the GI tract and may increase the risk for progression to thrombotic microangiopathy; these agents should be avoided. Nonsteroidal antiinflammatory agents may reduce renal blood flow and should also be avoided. Most experts believe that antibiotics increase the risk for progression to HUS, probably by lysing bacteria, releasing Stx and inducing bacteriophages on which Stx genes are expressed.

Transfusion Therapy in Thrombotic Microangiopathy

Patients with TTP often develop symptomatic anemia because of bleeding and partially compensated hemolytic anemia. Packed red blood cells can be transfused safely in this setting. In older adult patients and in those with an impaired cardiovascular system, it may be prudent to provide an additional margin of safety when choosing a threshold for transfusion. In contrast, platelet transfusions have historically been considered to be contraindicated in TTP based on several reports of patients under treatment for TTP whose clinical situation deteriorated within 1 to 24 hours of receiving allogeneic platelets. Clinical deterioration after platelet transfusion can also occur in patients with HUS, as well as Stx-associated and drug-induced thrombotic microangiopathies, and postmortem examination of such patients has revealed widespread microthrombi involving the brain, heart, lung, kidney, and multiple other organs. Sudden death has also been reported on rare occasions in patients who responded to plasma therapy with a rapid rise in the platelet count. However, a recent study assessing the effects of platelet transfusions administered to patients in the Oklahoma TTP-HUS registry suggests that platelet transfusion in patients with TTP is not linked with poor overall outcomes. In this study of 54 consecutive patients (47 with ADAMTS13 activity <10%), 33 (61%) received platelet transfusions. Platelet transfusion had no effect on the frequency of death or severe neurologic events, and no consistent temporal relationship was identified between platelet transfusion and clinical deterioration, regardless of whether transfusion was administered before or after initiation of plasma exchange. Two patients died from hemorrhage during central venous catheter insertion, one of whom had received platelet transfusion. Thus although it remains possible that platelet transfusion may exacerbate the course of TTP in occasional patients, more recent data make it difficult to implicate platelet transfusion as a common cause of clinical demise in TTP. Although most experts and the authors continue to believe that platelet transfusion should be avoided or minimized in these patients, the paradigm that platelet transfusion should be reserved only for life-threatening bleeding may require reexamination. In light of this, it seems reasonable to administer platelets to patients with TTP who are bleeding or those who are facing surgery or other invasive procedures in the setting of severe thrombocytopenia.

Activation of complement may contribute to the pathogenesis of Stx-HUS. Stx2 directly activates the alternative pathway of complement and binds to SCR 6-8 and 19-20 of factor H, which mediate surface recognition, blocking its ability to inhibit complement activation on cell surfaces. In support of this concept, eculizumab was reported to reverse neurologic abnormalities, low platelet counts, and elevated LDH levels in three patients with Stx-HUS. However, the value of complement inhibition in Stx-HUS remains to be established.

Atypical HUS

With the recent understanding of the role of the alternative complement pathway in the pathogenesis of aHUS, along with the development of aHUS registries containing patients who have undergone genetic analyses for mutations in alternative pathway proteins and inhibitors, it has become apparent that long-appreciated differences in response rates to plasma exchange in patients with aHUS correlate with genotype. The highest response rates to plasma exchange, 63% in an Italian registry, were seen in patients with CFH mutations, although complete responses occurred in only 5%. In contrast, only 25% of patients with CFI mutations responded to plasma therapy, with 75% progressing to death or end-stage renal disease. Response to plasma therapy in patients with mutations in cell-associated MCP was low, as expected; however, flares of disease in these patients often resolve spontaneously.

These results suggest that plasma therapy has a role in the management of aHUS, even if responses are not durable or complete. Moreover, when first evaluating a patient with TMA, information on ADAMTS13 levels or complement mutational analyses are generally not available, and thus initiation of plasma exchange therapy is reasonable.

Therapy for aHUS, however, is rapidly evolving with the recent approval of eculizumab, a neutralizing antibody to C5. Approval was based on as-yet unpublished data from two single-arm studies involving 37 adults and adolescents and a retrospective review of 19 pediatric patients and 11 adults (for important drug information, refer to http://www.accessdata.fda.gov/drugsatfda_docs/label/2011/125166s172lbl.pdf). These studies demonstrated activity of eculizumab in the majority of treated patients, whether or not they were refractory to plasma therapy. Several patients with severe renal insufficiency were able to discontinue dialysis.

These results suggest that eculizumab is the treatment of choice for patients with established aHUS or with a high clinical likelihood in an appropriate setting (e.g., postpartum status, positive family history, younger than 2 years of age). Additional studies are needed to define the role of this agent in adults presenting with new onset of TMA or in patients with normal ADAMTS13 levels who are refractory to plasma exchange.

Generally, patients with aHUS who progress to end-stage renal disease are considered candidates for transplantation. Before proceeding, complement genotypes should be determined to predict the risk for recurrence, which ranges from 75% to 90% in patients with CFH mutations to as low as 0% to 15% in patients with MCP mutations. In patients at high risk for recurrence, plasma or complement inhibitor therapy is recommended during and after transplantation.

Living related donor transplants are not recommended for patients with CFH, CFI, CFB, C3, or THBD mutations, and these transplants are questionable for patients with MCP or no observed mutations. The risk for development of aHUS in the remaining donor kidney also must be considered, as aHUS within several months of donation has been reported.

FUTURE DIRECTIONS

Thrombotic microangiopathic syndromes are uncommon, but their associated morbidity and mortality are significant. Over the last 5 years, dramatic progress has been made in our understanding of the pathogenesis of these syndromes, and these discoveries are being translated into effective therapeutic interventions. Eculizumab and other complement inhibitors may well change the natural history of aHUS from that of a progressive disorder culminating in chronic renal failure or death to a manageable chronic disease. Recombinant ADAMTS13 and targeted disruption of the vWF-GP1b interaction may prevent microvascular occlusion in TTP, while expanded use of anti-CD20 and other immunomodulatory approaches may reduce relapses and induce durable remissions. Finally, complement factor H concentrates have received orphan drug designation in Europe. Phase II trials of Stx antibodies are currently in progress.

A critical gray area in the understanding of TMAs is the factors that trigger onset and relapse. Why do some patients with acquired TTP have multiple relapses whereas others have none? Clearly, Stx triggers acute episodes of Stx-HUS, but other factors must account for the fact that some individuals with congenital deficiency of ADAMTS13 present in early childhood, while others may not develop disease until the fifth or sixth decades of life, if at all. Why is the penetrance of aHUS only 50% in the presence of a complement inhibitor gene mutation known to predispose to disease? Clearly, a better understanding of genetic susceptibility factors is essential, but equally important is identification of the environmental agents that incite disease, about which we now have little information.

CHAPTER 137

HEMOPHILIA A AND B

Manuel Carcao, Paul Moorehead, and David Lillicrap

EPIDEMIOLOGY

Hemophilia is the most common, severe inherited bleeding disorder recognized in humans. The hereditary and sex-linked nature of the disease has been appreciated since prebiblical times, and the previous occurrence of the disease in the European Royal family has added further interest in this condition.

The prevalence of hemophilia is worldwide, with no major geographical variances aside from rare clusters of disease in areas where founder mutations have been propagated. In many parts of the developing world, the true prevalence of the condition is unknown because of inadequate diagnostic facilities, but from experiences in the developed world, we can probably assume that the prevalence of hemophilia A is approximately one in 10,000 males and for hemophilia B, one in 50,000 males (Table 137-1). These prevalence figures do show some variances among countries but except where local founder effects are important, these differences likely represent variable disease ascertainment and diagnosis. Although because of the X-linked recessive inheritance of the disease, the significant majority of affected subjects are male, there are also significant numbers of carrier women who manifest clinical symptoms of bleeding because of low clotting factor levels.

International studies in the past decade indicate that the numbers of persons with hemophilia in the population is increasing by approximately 2% each year. There are likely several reasons for this trend, including the overall increase in population numbers and the increasing longevity of persons with hemophilia.

The clinical signs and symptoms and inheritance patterns for hemophilia A and B are identical, and it was not until the early 1950s that the two forms of hemophilia were differentiated. Subsequently, in the early 1980s, the two genes encoding factor VIII (FVIII) and factor IX (FIX) were cloned, and the specific mutations responsible for hemophilia began to be determined.

FACTOR VIII (FVIII) BIOLOGY: GENETICS, STRUCTURE, FUNCTION, AND PATHOPHYSIOLOGY

The Factor VIII Gene

The FVIII gene *(F8)* encoding the FVIII protein is located at Xq28, the most distal band of the long arm of the X chromosome (Fig. 137-1). It is a large and complex structure, 186 kb in length, consisting of 9 kb of exonic DNA arranged into 26 exons and 177 kb of intronic DNA in 25 introns. Most of the exons are small, ranging in size from 69 base pairs (exon 5) to 313 base pairs (exon 1), but exons 26 and 14 (encoding the central B domain) are 1958 and 3106 base pairs, respectively. The correspondence of these exons to the domains of the FVIII protein is described later. The size of *F8* introns varies from 207 base pairs (intron 17) to 32.4 kb (intron 22).

In addition to the 9-kb FVIII transcript, this locus also encodes two additional mRNAs that, unlike FVIII, are expressed ubiquitously. Within intron 22 of the *F8* gene there are two further coding elements, *F8A* and *F8B*. The *F8A* transcript is made up entirely of intronic sequence from intron 22, and the *F8A* mRNA is transcribed in the opposite direction to *F8*. Although the function of the F8A transcript/protein is unknown, there is the potential that this mRNA could act as an antisense regulator of FVIII expression. In addition, two (or more) other copies of the *F8A* sequence are located further telomeric to *F8* and are involved in a frequent intrachromosomal recombination event in approximately 45% of patients with severe hemophilia A. The *F8B* transcript is expressed in the same orientation as the native *F8* mRNA, and this transcript comprises an initial intron 22 sequence that is spliced onto exons 23 to 26 of *F8*. As with F8A, the F8B transcript is also ubiquitously expressed, and the function of the protein is unknown, but because it contains the phospholipid binding region of FVIII, it may play a role in membrane binding.

Factor VIII Expression

Transcription of the *F8* gene is regulated by a promoter that contains binding sites for both tissue-specific and ubiquitous transcription factors. The mRNA transcribed from *F8* is 9 kb in length and contains 7053 nucleotides of coding sequence and short 5′ and long 3′ untranslated sequences. The cellular site of FVIII expression has long been a matter of controversy. The situation is complicated by the very low abundance and instability of the FVIII transcript and protein. Nevertheless, F8 mRNA has been found to be expressed in a variety of human tissues, including hepatocytes, splenocytes, kidney cells, and muscle. However most recently, evidence suggests that there are two principal sites of FVIII synthesis, the liver and the vascular endothelium. It has long been known that hemophilia can be cured by liver transplantation, but the cell types within the liver responsible for FVIII synthesis have been unclear. There is now good evidence that both liver sinusoidal endothelial cells and, probably to a lesser extent, hepatocytes, express and secrete FVIII.[1] During episodes of severe liver failure, FVIII levels are maintained, providing strong support for sites of extrahepatic FVIII expression. The most likely extrahepatic source of FVIII expression is the endothelium. There are reports of the pulmonary vasculature producing FVIII, and it may well be that other vascular beds may also be involved in this process under certain circumstances.[2]

Factor VIII is an acute phase reactant, and studies have shown that FVIII expression can be induced through a nuclear factor kappa-B (NFκB)–mediated mechanism. FVIII levels also increase with hormone induction (estrogen use), but the mechanistic basis for this increase is not known.

The Biosynthesis of Factor VIII

Factor VIII biosynthesis has been extensively investigated in vitro using cell types that do not normally express this protein. Therefore, conclusions about the details of this process in a physiological context should be made with some caution. After production of the primary polypeptide chain and cleavage of the 19 amino acid signal peptide, the protein undergoes a series of posttranslational modifications,

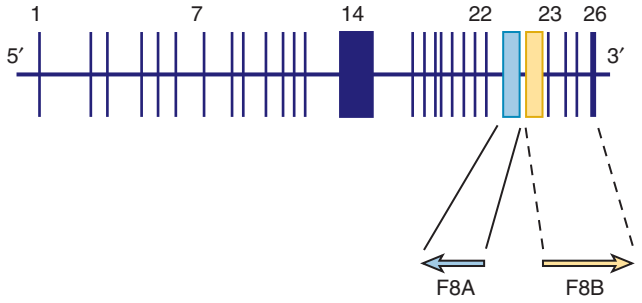

Figure 137-1 FACTOR VIII (FVIII) GENE. The FVIII gene *(F8)* is located on the X chromosome at cytogenic band Xq28-qter. The 26 exons span 184 kb of genomic DNA, and there are three open reading frames expressed from the locus: the 9 kb FVIII mRNA transcript incorporating all 26 exons of the gene; the F8A transcript that is transcribed in the opposite direction to FVIII and comprises sequences from intron 22; and finally, F8B comprising an initial 5′ exon derived from intron 22 sequence that is spliced to exons 23 to 26 of the *F8* gene.

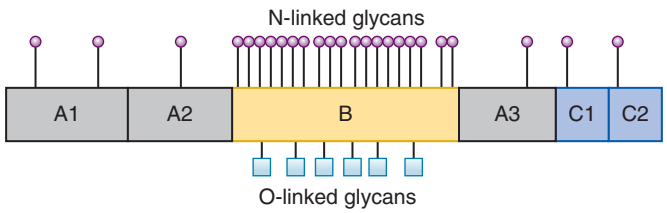

Figure 137-2 FACTOR VIII (FVIII) GLYCAN MODIFICATION (molecular weight, 260 kDa: plasma concentration, 100-200 ng/mL; 1 nM). The FVIII protein is modified by the addition of multiple N- and O-linked glycan chains. The majority of these glycan additions are located in the B domain and appear to play a role in facilitating intracellular trafficking and secretion of the protein.

including N- and O-linked glycosylation (mainly in the B domain) (Fig. 137-2) and sulfation of tyrosine residues. Furthermore, when the nascent protein transits the endoplasmic reticulum (ER), it interacts with ER chaperones, including calreticulin and immunoglobulin binding protein (BiP). Although these interactions limit the transport of malfolded or aggregated forms of the protein in heterologous cells with high levels of FVIII expression, their relevance in native FVIII-producing cells (i.e., a liver sinusoidal endothelial cell) is unknown. Indeed, under conditions of high-level FVIII expression, cells can activate a classical unfolded protein response and can succumb to apoptotic cell death.

The other detail of FVIII trafficking that has attracted attention is its transit between the ER and Golgi en route to secretion. Efficient transit through the ER–Golgi boundary appears to require an interaction with glycans within the B domain of the protein. Absence of these glycans or lack of specific transport proteins responsible for this trafficking event can significantly reduce the levels of secreted FVIII.

The Factor VIII Protein Structure

The DNA sequence of the *F8* gene predicts that the translated single chain polypeptide with a molecular weight of 260 kDa consisting of 2351 amino acid residues, including a 19-residue signal peptide. Upon translocation to the ER, the signal peptide is cleaved. The remaining polypeptide is 2332 residues long.

The FVIII protein consists of three types of domains: the three A domains, which have a 35% to 40% amino acid sequence homology to ceruloplasmin and factor V; a central B domain with no known homologues; and two C-terminal discoidin-like C domains that are also 35% to 40% homologous to factor V and ceruloplasmin (discoidin being a cell adhesion protein found in slime molds) (Fig. 137-3). There are also three small "a" domains (each between 20 and 40 amino acids) consisting of predominantly acidic residues. The sequence of these domains within the protein is NH2-A1-a1-A2-a2-B-a3-A3-C1-C2-COOH. Tyrosine residues in the a2 and a3 domains, when sulfated, contribute to the cofactor function of FVIII and enable its interaction with von Willebrand factor (vWF). As indicated, FVIII has structural similarities to coagulation factor V, which also has A and C domains 35% to 40% homologous to those in FVIII. However, FV does not contain a domain homologous to the B domain. Given these structural similarities, it is not surprising that both FVIII and FV function as cofactors for serine protease enzymes in the coagulation cascade, FVIII in the so-called intrinsic tenase complex and factor V in the prothrombinase complex.

Subsequent proteolysis of the FVIII polypeptide chain in the Golgi generates a light chain consisting of the A3-C1-C2 domains with a mass of 80 kDa (see Fig. 137-3).

Circulating FVIII exists as a heterodimer of the NH_2-terminus heavy chain and the COOH-terminus light chain. The two FVIII chains are bound to one another at the A1 and A3 domains by noncovalent bonds that are divalent metal ion dependent. The involved ion is likely copper, which has been found in association with FVIII.

Recently, two low-resolution crystal structures of B domain–deleted FVIII have been reported. These structures confirm prior proposals generated via molecular modeling in terms of the overall organization of the A and C domains, but higher resolution structures are required to resolve details of the location and orientation of individual residues.

Storage, Secretion, and Circulation of Factor VIII

After synthesis, FVIII is secreted into the circulation, where it forms a tight noncovalent complex with its multimeric partner vWF (Kd ≈0.2-0.5 nM). Whereas the plasma concentration of FVIII is 100 to 200 ng/mL (≈1 nM), the concentration of vWF is approximately 10 μg/mL (50 nM); thus the molar ratio of FVIII in the FVIII-vWF complex is about 1 to 50. The majority of vWF in plasma is synthesized and secreted by vascular endothelial cells. vWF binds to the a3 and C2 regions of FVIII through sequences in the D′/D3 region of the mature vWF monomer. Just as the cellular source of FVIII has long been argued, so, necessarily, has the site at which FVIII and vWF first interact. However, the recent finding that FVIII is expressed by at least some forms of endothelial cells suggests that some of the circulating FVIII may interact with vWF before secretion and may be co-stored with vWF in Weibel-Palade bodies. In the plasma, vWF protects FVIII from proteolysis by activated protein C. Without this interaction—for example, in cases of type 3 von Willebrand disease (in which vWF is absent) or type 2N von Willebrand disease (in which mutations occur in the FVIII binding region of vWF)—the plasma half-life of FVIII is reduced and, consequently, the plasma levels of FVIII are low.

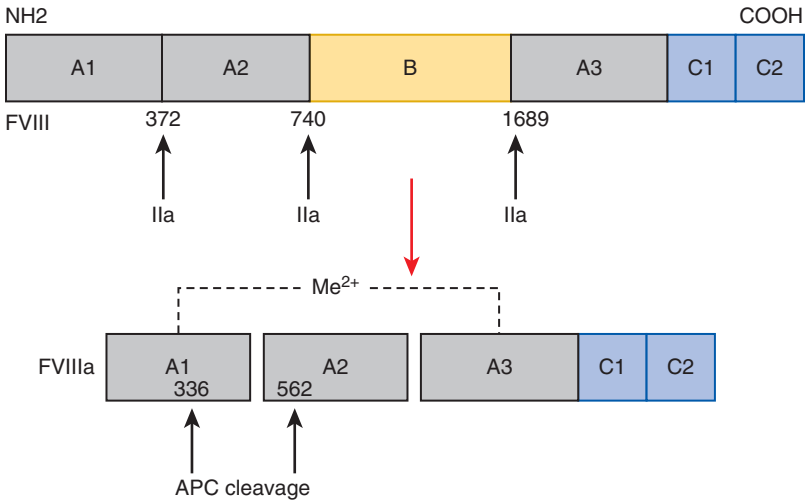

Figure 137-3 FACTOR VIII (FVIII) PROTEIN ACTIVATION AND INACTIVATION. The FVIII protein comprises a series of A and C domains that are homologous to FV and ceruloplasmin and a central B domain that does not show sequence homology. The inactive precursor protein is activated by thrombin through proteolytic cleavages at three locations. Inactivation of FVIIIa occurs through two mechanisms: spontaneous dissociation of the noncovalently bound A2 domain and proteolysis mediated by activated protein C (APC).

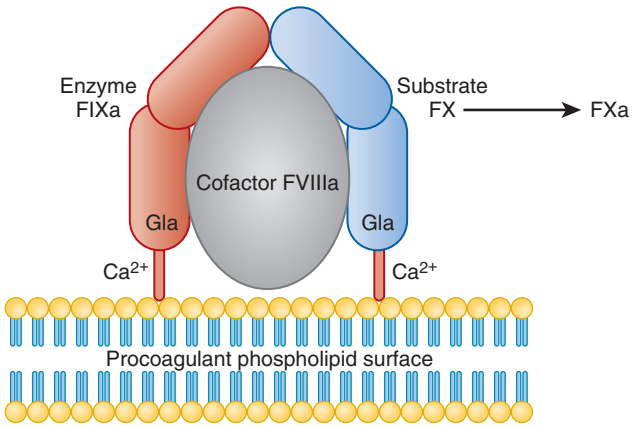

Figure 137-4 THE INTRINSIC TENASE COMPLEX. This membrane-bound complex plays an essential role in the amplification phase of hemostasis. Participation of all components of the complex enhances the catalytic efficiency of the factor Xa (FXa)–generating process by more than 200,000-fold. Deficiency or dysfunction of either the enzyme or cofactor involved in the complex results in a marked reduction in catalytic efficiency and the clinical manifestations of hemophilia. *FIXa,* Factor IXa; *FVIIIa,* factor VIIIa.

Activation and Coagulant Function of Factor VIII

Factor VIII plays a critical role in the propagation (amplification) phase of coagulation. The physiological activator of FVIII is thrombin, which proteolytically cleaves FVIII at three sites: Arg372 at the NH_2-terminus of the A2 domain, Arg740 at the NH_2-terminus of the B domain, and Arg1689 at the NH_2-terminus of the A3 domain (see Fig. 137-3). These cleavages release FVIII from vWF and result in the formation of a noncovalently associated A1-A2-A3/C1/C2 heterotrimeric activated FVIII (FVIIIa) molecule. FVIII can also be activated by FXa and FIXa, although the physiological contribution of activation by these proteases is less clear.

In its activated form, FVIII provides essential cofactor activity in the intrinsic tenase complex where FIXa is the serine protease and FX is the substrate (Fig. 137-4). This reaction takes place on a procoagulant phospholipid surface, which in normal hemostasis is likely the activated platelet. Participation of FVIIIa in the complex enhances the catalytic efficiency of this reaction about 200,000-fold, and thus severe FVIII deficiency profoundly reduces the rate of FXa generation and renders this reaction biologically futile. The exact details of the cofactor role of FVIIIa remain to be elucidated, but it is assumed that it acts as a "scaffold" protein that optimally aligns the enzymatic and substrate components of the complex on the phospholipid surface. Indeed, the FIXa and FX interactive regions of FVIII have been defined, and the cofactor binds to the phospholipid surface through hydrophobic residues in the C2 domain. Of note, the FVIII B domain is not required for cofactor function, and to date, it appears that the principal role of this region of the protein is to facilitate trafficking and secretion of the nascent polypeptide.

Factor VIIIa is inactivated through two processes. The predominant mechanism is through spontaneous dissociation of the A2 domain. The secondary inactivation event is via activated protein C–mediated proteolysis at Arg336 and Arg 562 in the FVIIIa heavy chain (see Fig. 137-3).

Our understanding of the clearance of FVIII/FVIIIa is limited. The low-density lipoprotein (LDL) receptor–related protein (LRP-1) and other members of the LDL receptor family contribute, but this is unlikely to be the complete story. Indeed, evolving evidence indicates that FVIII clearance may be mainly influenced by its multimeric partner, vWF, and that a group of receptors on macrophages, and possibly other cell types in the liver and spleen, may remove FVIII in complex with vWF.

Table 137-2 Genetic Mechanisms Causing Hemophilia in Females

- *F8* or *F9* mutation compound heterozygosity
- Extreme skewing of X inactivation process
- X/O karyotype: Turner syndrome
- X/autosome translocation

PATHOPHYSIOLOGY OF HEMOPHILIA A

Hemophilia A is a disorder characterized by congenital deficiency of FVIII. Almost all patients with hemophilia A have *F8* gene mutations. Because *F8* is located on the X chromosome, hemophilia A typically follows an X-linked inheritance pattern. As a result, males are affected most often. Severe and moderately severe cases of hemophilia A are unusual in females but can result from genetic mechanisms, including the following (Table 137-2): inheritance of either homozygous or compound heterozygous *F8* mutations; inheritance of a single *F8* mutation together with a 46 XO karyotype (Turner syndrome); inheritance of a single *F8* mutation and an X/autosome translocation; and, rarely, a markedly skewed inactivation of the X chromosomes that may, in some instances, involve a second genetic defect that prevents inactivation of the hemophilic X chromosome. Approximately 30% of hemophilia A cases are caused by a sporadic mutation and occur without a family history of the disorder.

The molecular genetic basis of hemophilia A has been extensively characterized over the past 25 years. A comprehensive Internet database of hemophilia A mutations is maintained and updated at http://hadb.org.uk.

In contrast to hemophilia B, a significant proportion of hemophilia A cases are the result of a recurrent mutation, an inversion mutation involving sequences in intron 22 of the gene (Fig. 137-5). The mechanism involved in generating this mutation involves an intrachromosomal recombination event in which there is an exchange between the F8A gene in intron 22 and one of two extragenic copies of this sequence that are located 5′ and telomeric to *F8*. The origin of this recurrent mutation is almost exclusively in the male germline, where the single X chromosome has no partner to pair with, thereby potentially facilitating the F8A-mediated intrachromosomal recombination. The result of this event is the inversion of the *F8* gene between exons 1 and 22 and thus, although two distinct *F8* transcripts are expressed from separate promoters (exons 1-22 and exons 23-26), a contiguous FVIII protein sequence is not synthesized. The intron 22 inversion mutation is always associated with a severe phenotype and is responsible for approximately 45% of the cases of severe hemophilia A.

A second recurrent inversion mutation involving intron 1 of the *F8* gene is responsible for approximately 2% of the cases of severe hemophilia A.

The remainder of the mutations responsible for hemophilia A involve more than 1000 different alterations with a wide array of missense, nonsense, frameshift, insertion or deletion, and splicing mutations. In addition, two transcriptional mutations have been identified in the F8 promoter region. All regions of the gene are potential mutation targets, but, as elsewhere in the genome, certain sequences, such as the CpG dinucleotide in arginine codons, are more prone to mutation because of spontaneous methylation of the 5′ cytosine and spontaneous deamination to thymine. To date, approximately 98% of cases of hemophilia A have been associated with mutations of the *F8* locus. The location of the missing mutations is not yet resolved, but the likelihood of locus heterogeneity for hemophilia A seems small. Indeed, the recent identification of mutations deep within introns of the gene suggests that all hemophilia A mutations are quite likely to be found within or adjacent to *F8*.

There have been extensive genotype and phenotype studies of hemophilia A with, in general, a good correlation between null mutations and severe disease and with many missense mutations and a moderate or mild phenotype. The phenotype remains consistent with a specific mutation both within and among families.

In addition to its utility for family counseling issues, the *F8* genotype has also been found to be a predictive factor for the development of anti-FVIII antibody development (Table 137-3). Thus multidomain deletions are associated with an approximately 75% risk of inhibitor development, a group of mutations including the intron 22 and intron 1 inversions, nonsense and insertion or deletion mutations are associated with a 20% to 30% inhibitor risk. Finally, a group of mutations including most missense and splicing mutants have an inhibitor risk of less than 10%.

FACTOR IX BIOLOGY: GENETICS, STRUCTURE, FUNCTION, AND PATHOPHYSIOLOGY

Factor IX Gene and Factor IX Expression

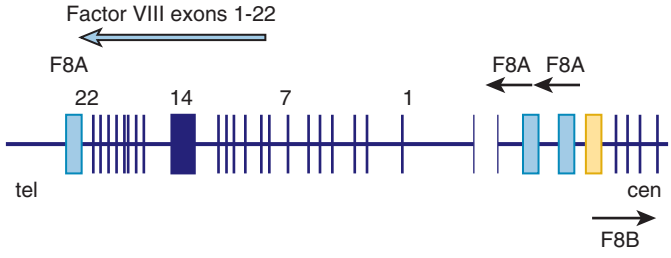
The gene that encodes FIX was cloned and characterized by two groups in the early 1980s. The gene is located on the X chromosome at cytogenetic band Xq27 and spans 34 kb of genomic sequence (Fig. 137-6). The eight exons of the *F9* gene encode an mRNA transcript of 1.4 kb that is expressed exclusively in hepatocytes. The transcriptional regulatory elements of the *F9* gene have been well characterized, and indeed, there is a variant form of hemophilia B, hemophilia B Leyden, in which a postpubertal rescue of inherited FIX deficiency is the result of an activated androgen response element in the *F9* proximal promoter.[3] Aside from this hormone responsive element, the *F9* promoter contains a typical combination of predominantly liver-specific transcription factor binding sites.

Factor IX Protein

Factor IX is synthesized exclusively in hepatocytes and circulates in plasma at a concentration of approximately 5 μg/mL (90 nM). The mature circulating protein consists of 416 amino acids and has a molecular weight of 57 kDa (Fig. 137-7). The protein is initially synthesized as a pre-propolypeptide with a short signal sequence, which facilitates entry into the ER, and a propolypeptide sequence, which interacts with the γ-glutamylcarboxylase in the ER. The interaction with this microsomal enzyme catalyzes the posttranslational

Table 137-3 Factor VIII Mutant Genotype and Inhibitor Risk in Previously Untreated Hemophilia A Patients

Multidomain deletions	≈75%
Light chain nonsense mutns	30%-40%
Intron 22 inversion	20%-25%
Single domain deletions	15%-25%
Small non-A run insertions/deltns	15%-20%
Heavy chain nonsense mutns	10%-20%
Factor VIII missense mutns	<10%
Small A run insertions/deltns	<5%
Splicing mutns	<5%



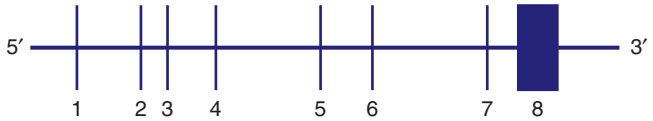


Figure 137-5 THE *F8* INTRON 22 INVERSION MUTATION. In about 45% of severe hemophilia A patients, there is a recurrent *F8* inversion mutation involving intrachromosomal recombination of F8A sequences within intron 22 of the gene and at a 5′ telomeric location. This mutation always results in a severe phenotype and almost always originates in the male germline.

Molecular pathology of hemophilia B

- No predominant recurring mutation
- Majority of mutations are missense variants
- Some mild phenotypes are due to founder mutations

Figure 137-6 THE FACTOR IX GENE *(F9)*. The *F9* gene is located on the long arm of the X chromosome at cytogenetic band Xq27 centromeric to the *F8* gene and the common X chromosome fragile site. The gene comprises 34 kb of genomic DNA arranged in eight exons.

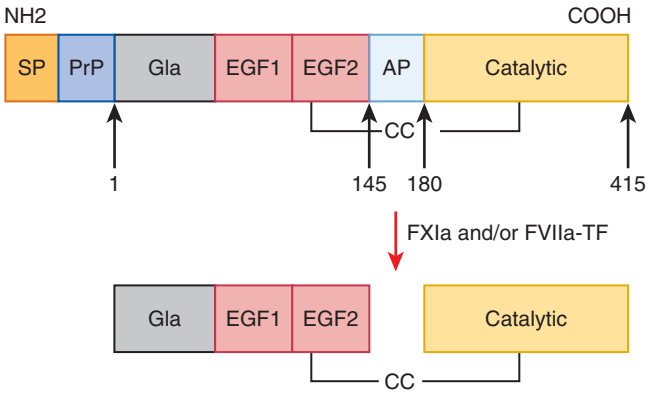

Figure 137-7 THE FACTOR IX (FIX) PROTEIN (415 amino acids; 57 kDa; plasma concentration, 5 μg/mL; 90 nM). FIX is synthesized exclusively in hepatocytes. The protein is produced initially as a pre-propolypeptide. The signal peptide (SP) is cleaved upon entry into the endoplasmic reticulum (ER), and the propeptide (PrP) is also removed in the ER after γ-carboxylation of 12 glutamic acid residues in the *N*-terminal Gla domain. Factor IX is activated by proteolytic removal of the activation peptide (AP), and FIXa is inactivated through complex formation with antithrombin *CC,* Disulfide linkage; *EGF,* epidermal growth factor-like domain..

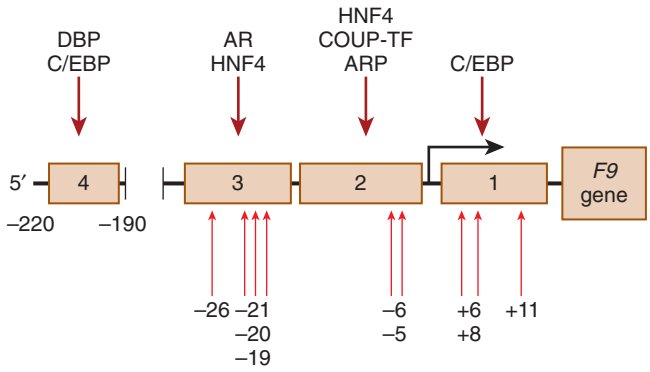

Figure 137-8 MUTATIONAL BASIS OF HEMOPHILIA B LEYDEN. In this variant form of hemophilia B, patients experience a spontaneous recovery of factor IX (FIX) levels after puberty. The disease results from mutations in the *F9* promoter that disrupt transcription factor binding. Postpubertal recovery is at least partly attributable to the expression of testosterone, with the subsequent activation and binding of the androgen receptor to its cognate sequence in the *F9* promoter. Sites 1 to 4 are transcription factor binding regions. *AR,* androgen receptor; *C/EBP,* CCAAT enhancer binding protein; *COUP-TF,* chicken ovalbumin upstream transcription factor; *DBP,* D site binding protein; *HNF-4,* hepatocyte nuclear factor 4.

conversion of the amino-terminal 12 glutamic acid residues of mature FIX into γ-carboxyglutamyl residues (the GLA domain). This posttranslational modification enables FIX to form calcium-dependent interactions with procoagulant phospholipid membranes. A second posttranslational modification at residue 64 in the first epidermal growth factor (EGF)–like domain of the mature polypeptide involves β-hydroxylation of asparagine. This modification also plays a role in facilitating interactions with calcium and phospholipid membranes.

The structure of FIX is homologous to that of other vitamin K–dependent coagulation proteins. The domain structure includes an amino-terminal GLA sequence followed by two EGF-like domains, an activation peptide and the carboxyl-terminus catalytic domain, which is similar to the organization of the procoagulant factors VII and X and to the anticoagulant protein C.

The FIX zymogen is activated by two processes, proteolytic cleavage mediated by FXIa and by a similar process involving the FVIIa–tissue factor complex. The activation of FIX involves sequential proteolysis of two peptide bonds at arginine residues 145/146 and 180/181 (see Fig. 137-7). These cleavages release the FIX activation peptide and result in the formation of the disulfide-linked FIXa enzyme with an NH_2-terminus light chain and COOH-terminus heavy chain. Whereas the light chain binds to procoagulant phospholipid surfaces through a calcium-mediated process involving the GLA domain, the C-terminus catalytic domain cleaves and activates the substrate factor X. This reaction involves the so-called intrinsic tenase complex in which activated FVIII participates as an essential cofactor. Absence of FVIIIa in the tenase complex reduces the catalytic efficiency of the reaction by approximately 200,000-fold.

Factor IXa is inhibited through an interaction with the natural anticoagulant protein antithrombin. The fate of FIXa–antithrombin complexes is not well characterized, but specific antithrombin–protease receptors on the surface of hepatocytes participate in this process.

Hemophilia B Molecular Pathology

To date, all of the mutations responsible for hemophilia B have involved the FIX gene. Although there is a combined vitamin K–dependent protein deficiency state that involves mutations of the γ-glutamylcarboxylase gene, this condition is characterized by low levels of FVII, FX, and prothrombin as well as FIX. Mutational analyses of large numbers of patients with hemophilia B have detected mutations in the FIX gene in more than 98% of cases, and it may well be that the remaining mutations are located within intronic sequences that have not yet been analyzed.

In marked contrast to hemophilia A, in which approximately 50% of mutations resulting in severe disease are caused by two recurrent gene inversion events, approximately 75% of mutations in hemophilia B are missense substitutions. There are no common recurrent FIX mutations, although mild forms of hemophilia B may show a founder effect of missense variants in some populations.

Aside from the predominance of missense mutations, multiple other mutations can produce hemophilia B ranging from large gene deletions to a mix of nonsense, insertion or deletion, and splicing changes. The full array of FIX mutations responsible for hemophilia B can be reviewed in an Internet-accessible database at http://www.kcl.ac.uk/ip/petergreen/haemBdatabase.html. The following text highlights several distinct and clinically important hemophilia B mutations.

The most biologically remarkable hemophilia B mutations are those that produce hemophilia B Leyden, a disorder wherein FIX levels gradually increase from less than 5% at birth to greater than 30% by early adulthood. Because of the low FIX levels early in life, boys with this disorder often have bleeding episodes and experience clinical symptoms and signs consistent with these. After puberty, these problems resolve or improve, and a frequent story told by individuals in these families is that a misdiagnosis of hemophilia was made during childhood. All of the hemophilia B Leyden point mutations are located in a 40-bp region of the FIX promoter around the transcriptional start site (Fig. 137-8). Each of these mutations interferes with the binding of a liver-specific transcription factor, and thus, up to the time of puberty, levels of FIX expression are markedly reduced. After puberty, there is synthesis of testosterone and androgen receptor activation. Binding of testosterone to an androgen response element in the FIX promoter provides a rescue mechanism for the disrupted FIX transcriptional status. Thus any family in which a previously diagnosed hemophilia B subject now appears normal should be investigated for a promoter mutation.

Since the cloning of the FIX gene in the 1980s, the association of *F9* gene deletions with FIX antibody formation has been well recognized. Thus, with partial and complete *F9* deletion mutations, the risk of development of a FIX antibody response is between 30% and 50%. In addition to neutralizing FIX enzymatic function, these antibodies can also be associated with anaphylactic or anaphylactoid reactions to FIX infusions.[4] The antibodies usually develop in young children (1-2 years old) after 10 to 20 exposures to FIX concentrate.

FIX concentrate use is no longer of benefit in most of these patients, and attempts at inducing immunologic tolerance to FIX may be complicated by the development of nephritic syndrome. The mechanism underlying this complication is currently unresolved.

Hemophilia is the bleeding disorder commonly associated with past members of the Royal families of Europe. Although the clinical picture in these individuals was consistent with severe hemophilia, the precise diagnosis was not reported until 2009. In fact, a diagnosis of hemophilia was confirmed, but not hemophilia A as had been thought and would have been expected on the basis of disease incidence, but hemophilia B (Fig. 137-9).[5] The "royal" *F9* mutation is a splicing variant occurring at the 3′ end of intron 3 that creates a new splice acceptor sequence that results in a novel out-of-frame transcript with 11 new amino acids followed by a premature stop codon. This mutation likely leads to either nonsense-mediated accelerated decay of the mutant FIX mRNA or to the translation of a significantly truncated nonfunctional FIX protein. In both instances, the clinical phenotype would likely have been severe.

Missense mutations elsewhere in the FIX gene have been informative with regards to our detailed understanding of protein structure and function. Mutations at both activation peptide cleavage sites have been described, and as with many genes, recurrent "hotspot" mutations have been documented at arginine codons with CpG dinucleotide sequences. Finally, some mild and frequently encountered FIX variants appear to be caused by founder mutations, as evidenced by a common adjacent polymorphic haplotype.

Hemophilia Diagnosis

The initial diagnosis of hemophilia depends to some extent on the family context. In families in which hemophilia has previously been identified, family counseling determines the risk of hemophilia transmission and usually results in a diagnosis being made in utero or early in neonatal life. In contrast, when there is no family history of the disease, the diagnosis will often not be made until there are signs of a bleeding diathesis, and the timing of this depends on the extent of factor deficiency. In severe deficiency states, the diagnosis is often made in the first 1 to 2 years of life, but with moderate and mild disease, the diagnosis may be made much later; with mild hemophilia, the diagnosis may be delayed until late adult life when bleeding occurs after a surgical intervention.

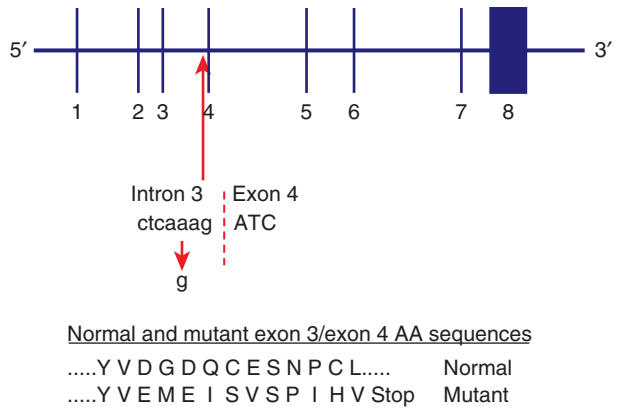

Figure 137-9 THE "ROYAL" HEMOPHILIA MUTATION. There is now definitive evidence that the hemophilia previously present in the European royal families was hemophilia B. The point mutation found in an affected male from the Russian royal family introduces a new acceptor splice site at the 3′ end of intron 3 of the *F9* gene. The consequence of this change is the translation of 11 novel amino acids from the exon 3/4 boundary followed by a premature stop codon. A severe phenotype would be expected either because of accelerated mRNA decay or the synthesis of a nonfunctional truncated factor IX protein. *(Data from Rogaev EI, Grigorenko AP, Faskhutdinova G, et al: Genotype analysis identifies the cause of the "royal disease."* Science *326:817, 2009.)*

Phenotypic Diagnosis of Hemophilia

Two diagnostic strategies can be used for hemophilia. In the vast majority of cases, this involves measurement of FVIII or FIX coagulant levels in platelet poor plasma using a functional clotting assay (usually a one-stage PTT-based assay). Although most clinical hemostasis laboratories use a one-stage PTT-based test to quantify FVIII, some laboratories use either a two-stage assay or a chromogenic substrate assay that measures the generation of FXa in a purified system (Table 137-4). In these latter assays, the incubation time is often longer, which may influence test results. For example, a group of mild hemophilia A missense mutations results in the synthesis of an unstable FVIII with enhanced dissociation of the A2 domain from the remainder of the protein. These unstable mutants can sometimes be missed when a one-stage FVIII assay is used but are readily apparent with two-stage or chromogenic assay protocols that use a prolonged incubation time.

The severity of hemophilia is based on the extent of clotting factor deficiency (severe, <1% [<0.01 U/mL]; moderate, 1%-5% [0.01-0.05 U/mL]; and mild, 5%-40% [0.05-0.40 U/mL]). When making a diagnosis of hemophilia B, caution must be taken in neonates because levels of FIX can be low in normal newborns as a result of an immature carboxylase system. It is advisable to wait for 1 month to confirm the baseline level of FIX in cases of apparent mild hemophilia B.

Genetic Diagnosis of Hemophilia

The other diagnostic strategy that can be used in hemophilia involves the use of DNA analysis. Since the cloning of the FVIII and FIX genes in the early 1980s, molecular genetic approaches to hemophilia diagnosis have advanced dramatically.

Currently, mutations responsible for hemophilia A and B can be identified in the F8 and F9 genes in approximately 98% of cases. In cases in which mutations have not been found, it is likely that sequence changes are deep within introns or within distant regulatory elements, regions of the genes that are not routinely examined in diagnostic laboratories.

The strategy for genetic analysis depends on the type of hemophilia and the severity of the phenotype. For example, all patients with severe hemophilia A should be screened initially for the recurrent F8 intron 22 and intron 1 inversion mutations. In contrast, most patients with hemophilia B require full-sequence analysis of the entire FIX promoter, coding region, and splice sites.

When a familial mutation has already been identified in the FVIII or FIX gene, a prenatal diagnosis can be made by either chorionic villus sampling or amniocentesis. Outside of the prenatal context, mutation testing in hemophilia can be used for carrier detection for family planning purposes and as one component of the risk analysis for inhibitor development. In hemophilia A and B, large gene deletions are associated with a higher risk of inhibitor formation soon after exposure to clotting factor therapy, and in hemophilia B, there is also the risk of anaphylactic reactions in these patients.

Table 137-4 Methods of Factor VIII Measurement

1. FVIII antigen ELISA (rarely used clinically)	
2. FVIII functional assay	
a. One-stage clotting assay: >98% of clinical laboratories; assay CV <10%	
b. Chromogenic assay	May detect FVIII instability mutants
c. Two-stage clotting assay	May detect FVIII instability mutants
3. Indirect measurement	
Global assays (e.g., thrombin generation assay)	

CV, Coefficient of variation; *ELISA,* enzyme-linked immunosorbent assay; *FVIII,* factor VIII.

Determination of the hemophilic genotype is now regarded as the standard of care in comprehensive hemophilia treatment centers (see box on Hemophilia Carrier Detection and Prenatal Diagnosis).

Diagnosis of the Carrier State in Hemophilia

The X-linked recessive nature of hemophilia naturally results in the majority of affected subjects being males. Females, however, carry and transmit the hemophilic trait and can sometimes also express clinical manifestations of the disease. Although there are rare genetic circumstances that can result in moderately severe or severe hemophilia in women (see Table 137-2), the majority of females with low FVIII or FIX levels do so because of variable skewing of the random X inactivation process that takes place early during embryonic development.

There are four ways in which hemophilia carriers can be identified. First, in light of the X-linked transmission of the disease, pedigree analysis will determine the carrier status of some women. Thus all daughters of hemophilic fathers are obligate carriers, and 50% of the daughters of a hemophilia carrier mother will also carry the mutant allele. The second mode of identification can be through the manifestation of abnormal bleeding caused by a low FVIII or FIX level. Estimates of the percentage of hemophilia carriers who experience excessive bleeding (most often demonstrated through menorrhagia) vary but likely approximate 20% to 30%. The third mode of carrier detection involves use of the laboratory phenotype, in which tests of the intrinsic pathway (PTT) may be abnormal and the plasma levels of FVIII or FIX may be reduced below the normal range. Finally, and most definitively, molecular genetic analysis provides precise determination of the hemophilic carrier state. This advance has significantly enhanced family counseling for hemophilic kindred and has also enabled women and their caregivers to prepare optimally for the delivery of newborns.

Hemophilia Carrier Detection and Prenatal Diagnosis

As an X-linked recessive trait, hemophilia most often manifests in males. However, females may be affected by the condition in two ways: through bleeding caused by low clotting factor levels and through transmission of the trait to later generations as a hemophilia carrier.

Women who are heterozygous carriers of a hemophilic mutation may have low levels of the implicated clotting factor. This depends on the ratio of inactivation of the hemophilic and normal X chromosomes, a random process that occurs early during embryonic development. If there is markedly skewed inactivation of the normal X chromosome, the plasma level of FVIII or FIX may be correspondingly reduced, and the carrier female may have evidence of a bleeding disorder. Thus FVIII or FIX levels should be determined in all potential carrier females before adolescence when they might first manifest with menorrhagia. A low plasma level of FVIII or FIX is predictive of the carrier state, and the lower the level, the more probable the carrier diagnosis.

Aside from using clotting factor levels to determine carrier status and bleeding risk, the most definitive approach to carrier diagnosis is to use molecular genetics to identify the causative FVIII or FIX mutation. Although carrier detection studies originally used analysis of linked polymorphisms to track mutant alleles, advances in sequencing technology now enable relatively easy access to direct mutation detection.

Ideally, carrier detection should be performed after puberty but before the woman is contemplating starting a family. In many countries, testing for the carrier status of genetic disease is prohibited before adolescence so that the girl can participate in discussions of testing options.

With current molecular genetic testing strategies, the results of mutation analyses are available within a few days in urgent circumstances. However, most often, results are returned within a few weeks.

Causative mutations in the FVIII or FIX genes are found in more than 95% of carriers. If a mutation is not found, it is possible that the mutation is deep within an intron or involves a distant transcriptional element.

Prenatal diagnosis of hemophilia should begin with an evaluation of the fetal sex, which can usually be determined through an ultrasound examination. If the fetus is female, no additional studies should be performed. If the fetus is male, molecular genetic analysis can be used to identify the hemophilic mutation. Fetal DNA can be isolated from chorionic villus samples obtained after 11 weeks of gestation or from amniocytes obtained by amniocentesis from 12 to 34 weeks. The risk of miscarriage with both of these procedures is approximately 1%. If the studies are being used for decision making concerning therapeutic abortion, the tests should be performed as soon as possible. Determination of the hemophilic status of the fetus will also help plan for delivery, although consensus about the optimal obstetric management of an affected baby is lacking. Finally, recent studies suggest that free fetal DNA can be isolated from the mother's blood, with levels increasing towards term. Examination of this material for the presence of Y chromosome sequences would allow definitive sex determination.

Differential Diagnosis of Hemophilia

The initial clinical suspicion of hemophilia will usually come from signs and symptoms of excessive bleeding, a family history of a bleeding problem, or abnormal coagulation test results.

There are many causes of mild bleeding manifestations, such as increased bruising and prolonged bleeding after dental and surgical procedures. These include either isolated or combined deficiencies of other clotting factors (i.e., FXI, FVII, FX, FII, FV deficiency; see Chapter 139), von Willebrand disease (vWD; see Chapter 140), or various quantitative or qualitative platelet pathologies (see Chapters 132 to 134). Acquired bleeding symptoms can be caused by antithrombotic drugs (e.g., antiplatelet agents and anticoagulants) or can result from autoantibodies against clotting factors (e.g., acquired hemophilia A or vWD).

The differential diagnosis of a low plasma FVIII level is relatively straightforward (Table 137-5). Levels of FVIII below 10% are likely the result of inherited or acquired hemophilia A or a severe form of inherited or acquired vWD (severe type 1 or type 3 vWD). Determination of vWF antigen and vWF ristocetin cofactor levels is essential for diagnosis. Occasionally, levels of FVIII below 10% can be attained with type 2N vWD. This diagnosis can be confirmed using FVIII binding studies or by genotypic analysis of the FVIII binding codons of vWF (exons 17-25, which encode the D′/D3 regions of the vWF protein).[6] Levels of FVIII between 10% and 50% are also

Table 137-5 Differential Diagnosis of a Low Factor VIII Level

1. FVIII <10%
 - Severe or moderately severe hemophilia A
 - Severe type 1 vWD
 - Type 3 vWD
 - Type 2N vWD
 - Acquired hemophilia A
 - Acquired vWD
2. FVIII: 10% to 50%
 - Mild hemophilia A
 - Type 1 vWD
 - Type 2N vWD
 - Combined FVIII and FV deficiency

FV, Factor V; *FVIII,* factor VIII; *vWD,* von Willebrand disease.

likely the result of either hemophilia A or vWD (types 1 or one of the type 2 variants, 2A, 2B, 2M, or 2N). Assessment of vWF levels must be undertaken in these cases; if the vWF:RCo/vWF:Ag ratio is below 0.6, further evaluation of a possible type 2 variant must be pursued. Rarely, mild or moderate FVIII deficiency can be co-inherited with FV deficiency (see Chapter 139). Combined inherited deficiency of FVIII and FV (levels are usually between 5% and 20%) has a prevalence of approximately 1 per million. This rare inherited trait is caused by recessive mutations in one of two genes involved in the facilitation of protein transport across the ER-Golgi interface: lectin mannose binding protein type 1 (LMAN1) or multiple coagulation factor deficiency 2 (MCFD2).

Isolated low plasma levels of FIX are almost always caused by congenital hemophilia B. Interestingly, in contrast to acquired hemophilia A, autoantibody development against FIX is rarely encountered. Other situations in which FIX deficiency is found usually involve concomitant reductions in the other vitamin K–dependent clotting factors, such as occurs with vitamin K antagonists, vitamin K deficiency, or significant liver disease. A much less common cause of a mild deficiency state of all of the vitamin K–dependent proteins is an inherited defect in the γ carboxylase enzyme required for the posttranslational modification of these proteins.

CLINICAL FEATURES OF HEMOPHILIA

The clinical symptoms and signs of hemophilia A and B are identical and relate to the propensity for prolonged and excessive bleeding. The bleeding tendency in hemophilia is determined in large part by the baseline level of the deficient or defective clotting factor. Thus, in severe hemophilia (A and B), in which the baseline level of clotting factor is below 1% (0.01 U/mL), spontaneous bleeding usually occurs multiple times each year. With a mild factor deficiency state of 1% to 5% (0.01-0.05 U/mL), spontaneous bleeding is infrequent, but excessive and prolonged bleeding can occur with trauma and invasive surgical or dental procedures. Finally, in mild disease, with factor levels of 5% to 40% (0.05-0.40 U/mL), excessive bleeding is usually only documented with trauma or invasive procedures.

Pathological bleeding can occur in the neonatal period, when intracranial bleeding can develop after traumatic delivery, especially in infants with severe hemophilia. However, most frequently, severe disease manifests with easy bruising or soft tissue or joint bleeding between 6 and 18 months of age when the young child becomes more mobile. In mild hemophilia, the disease may remain silent for many years, and occasionally a new diagnosis of hemophilia may be made in those older than 60 years of age when challenged with a surgical procedure.

The bleeding pattern in severe hemophilia is distinct and is not often seen in other bleeding disorders. In severe hemophilia, the development of hemarthroses is a classical clinical sign. Bleeding into the ankles, knees, and elbows is seen most frequently, although a hemarthrosis can occur in any joint (e.g., into the temporomandibular joint). The development of a hemarthrosis is accompanied by pain, swelling, and reduced mobility, but after repeated episodes of joint bleeding, most patients with hemophilia are able to discern intraarticular bleeding at a very early stage before any of the classical clinical signs are apparent. Repeated bleeding into a single joint results in the development of a "target joint," one in which further bleeding episodes are facilitated by previous events, leading to a vicious cycle of joint damage. With repeated episodes of bleeding, the joints become painful and less mobile. Eventually, this can result in immobility and muscle wasting of the affected limb (Fig. 137-10).

In addition to joint bleeding, patients with hemophilia are prone to excessive and prolonged soft tissue and mucocutaneous bleeding. Bleeding into unusual sites, such as the iliopsoas muscle, can result in prolonged disability, and rarely, intracranial bleeding can develop, most often after trauma.

Although bleeding is the hallmark of hemophilia, the types of bleeds and issues vary somewhat according to the age of the patient. This is particularly the case in newborns with hemophilia who have specific issues related to the birthing process not encountered later on in life. Also, the issues encountered in infancy (the highest risk period for developing inhibitors and the time for establishing home care and prophylaxis protocols) are different from those encountered in later childhood, adolescence, and the early and late adult years.

Figure 137-10 CLINICAL OUTCOME OF CHRONIC SEVERE HEMOPHILIC ARTHROPATHY. This picture shows the legs of a 55-year-old patient with severe hemophilia A who is a wheelchair user. After a lifelong experience of multiple hemarthroses, the patient has very limited mobility. His ankles and knees show deformities, and his leg muscles are markedly atrophic because of a lack of use.

Hemophilia in Newborns

The neonatal period is a particularly hazardous period for newborn children with severe hemophilia. Newborn babies with hemophilia can be born to mothers who are known or suspected of being carriers or can be born to mothers who are not known to be carriers. The latter occurs in about 30% of newborns with hemophilia. It is principally in the group of children born to families with no history of hemophilia that the risk of severe bleeding is greater because no precautions are taken to avoid bleeding. How best to deliver children known to have severe hemophilia is still a matter of debate. For the most part, physicians still recommend an atraumatic vaginal delivery because this can usually be performed safely and avoids the increased maternal morbidity associated with cesarean section. Furthermore, delivery of a child by cesarean section does not completely eliminate the risk of intracranial hemorrhage (ICH) (Fig. 137-11). The use of vacuum extraction or forceps should be avoided because these procedures increase the risk of both extracranial (e.g., subgaleal hemorrhage and cephalohematoma) and ICH. Fetal blood sampling has not been shown to be a significant risk factor for ICH.

Intracranial Hemorrhage in Newborns

The incidence of ICH in newborn children with severe hemophilia varies from 3.5% to 4%.[7] It is surprising that it is this low given the

Figure 137-11 INTRACRANIAL BLEEDING IN HEMOPHILIA. A computed tomography scan shows an intracranial bleed in a person with hemophilia. This complication most often occurs after trauma with an incidence of five per 1000 per year in patients younger than age 5 years and 1% to 2% per year in persons with hemophilia older than age 55 years.

trauma of childbirth. Nevertheless, this is still 40- to 80-fold higher than that in the normal nonhemophilic population. If a child with known hemophilia shows any sign of ICH, prompt infusion of the appropriate factor concentrate should be undertaken. If the type of hemophilia is not known, fresh plasma can be given at a dose of 10 mL/kg. Because FVIII deficiency is more common than FIX deficiency, an alternative is to administer FVIII concentrate and determine the PTT 10 to 15 minutes later. If the patient has hemophilia A, the PTT should correct. If the PTT does not correct, then it can be assumed that the child has FIX deficiency, and an appropriate FIX concentrate can be given. If a FVIII concentrate is used, fresh plasma can be given while waiting for the PTT results to cover the possibility that the child has hemophilia B.

In newborn boys without a family history of hemophilia, signs of ICH (e.g., unequal pupils, seizures, vomiting, and lethargy) should prompt an urgent PTT determination along with central nervous system imaging. If the PTT is prolonged and imaging studies reveal an intracranial bleed, levels of FVIII, FIX, and vWF should be determined urgently. While waiting for the results of these levels, it is best to treat the patient with a FVIII concentrate, or plasma can be given.

Circumcision in Newborns

Surprisingly, bleeding after circumcision only occurs in about half of patients with severe hemophilia. Consequently, the lack of bleeding after circumcision does not exclude hemophilia. In children who are suspected of having hemophilia, the hemophilic status should be confirmed before circumcision. If hemophilia is proven and the family still wishes to undertake circumcision, the appropriate factor concentrate should be administered to the child before the procedure. Generally, a single dose is sufficient.

Other Bleeding Manifestations in Hemophilia

Although virtually all types of bleeds can occur in hemophilia, musculoskeletal bleeds (hemarthrosis, muscle bleeds, and hematomas) are most common and cause the most long-term complications. Other reasonably common bleeds include oral, dental, gastrointestinal (GI), genitourinary, and neurologic bleeding. Additionally, insufficiently treated muscle and soft tissue bleeds may develop into pseudotumors (see box on Hemophiliac Pseudotumors) or lead to compartment syndrome (see box on Compartment Syndrome). Finally, bleeds can occur in the context of surgery and dental procedures.

Bleeding in hemophilia is broadly correlated with the endogenous level of clotting factor. Patients with severe forms of hemophilia defined as having an endogenous FVIII or FIX level of less than 1% (<0.01 U/mL) will develop spontaneous bleeds throughout their lives beginning at about 6 to 12 months of age when beginning to crawl. Without prophylaxis, patients with severe hemophilia develop more bleeds as they age, and studies have shown that on average such patients experience 20 to 30 bleeds per year. Patients with moderate hemophilia (FVIII or FIX level of between 1% and 5% [0.01 and 0.05 U/mL]) and those with mild hemophilia (factor levels of >5% [>0.05 U/mL]) generally experience bleeding only in the context of trauma or surgery.

Both hemophilia A and hemophilia B are characterized by similar types of bleeds. However, the severity and frequency of bleeding may vary considerably among individuals with the same factor activity level, and the bleeding phenotype in hemophilia B seems to be less severe than that in hemophilia A with comparable factor levels. This is reflected in increased joint arthroplasty, increased use of prophylaxis, and a lower median age at start of prophylaxis in patients with severe hemophilia A compared with those with severe hemophilia B. Similarly, although a considerable proportion of children with moderate hemophilia A in Canada are on prophylaxis, few children with moderate hemophilia B are treated with prophylactic regimens, again suggesting a differential severity of hemophilia A and B. The reason for this difference in clinical bleeding severity between hemophilia A and B has not been well studied. For patients with severe hemophilia, one possible explanation is related to the genetics of hemophilia. Patients with severe hemophilia B generally have non-null mutations (e.g., missense mutations) and as such are likely to have some, albeit minimal, endogenous FIX activity. In contrast, most patients with severe hemophilia A have null mutations and produce no functional FVIII. Another theoretical reason to explain the difference in the severity of bleeding is that when patients with hemophilia B experience a bleed, their FVIII levels may rise because FVIII is an acute phase reactant. Because it serves as a cofactor for FIX, this increase in FVIII may augment the activity of the very low level of FIX that exists in patients with mild, moderate, or non-null mutation severe FIX deficiency, thereby improving the patients' hemostatic potential and limiting bleeding.

Even within patients with the same mutation and thus with the same endogenous level of clotting factor, there may be differences in bleeding predisposition. Reasons to account for this include the co-inheritance of other bleeding diatheses (e.g., vWD or mild functional platelet disorders) or prothrombotic disorders (e.g., factor V Leiden; prothrombin G20210A mutation; low levels of protein C, protein S, or antithrombin). Additional reasons to account for between-patient heterogeneity include varying levels of physical activity; differences in the pharmacokinetic handling of factor that might be associated with patients' ABO blood group and endogenous levels of vWF; and differences in the structural integrity of joints, making patients more or less susceptible to joint bleeds and joint damage. The latter may explain why some patients can experience one significant joint bleed and end up developing signs and symptoms of chronic hemophilic arthropathy but other patients may not develop joint damage despite repeated joint bleeding.

Soft Tissue Hemorrhages and Muscle Bleeds

Bleeding into soft tissues includes spontaneous and trauma-related bleeding into subcutaneous tissues and muscles. Superficial

hematomas (bruises) may resolve spontaneously without the need for treatment, and as such, bruising is not an indication to treat the patient with clotting factor replacement. However, in moderate and severe hemophilia, soft tissue hematomas often undergo progressive enlargement and may need to be treated. Furthermore, some soft tissue bleeds (e.g., retroperitoneal bleeds or hematomas of the neck) may cause extensive blood loss and be life or organ threatening because of their propensity to expand, thus causing compression of adjacent organs, blood vessels, and nerves and, in the case of neck hematomas, compromise of the airway.

Muscle bleeds are quite common in hemophilia. The muscles most often involved are, in descending order of frequency, the calf, thigh, buttocks, and forearm. Bleeds into these locations can lead to compartment syndrome, which is an emergency situation (see box on Compartment Syndrome).

A particularly problematic muscle bleed is a bleed into the iliopsoas muscle, a large muscle in the hip region. Such bleeds can rapidly expand because there is no surrounding connective tissue to restrict their growth. Consequently, significant bleeding can occur into this muscle, potentially leading to the need for blood transfusion. Patients with iliopsoas muscle bleeds have pain and restriction of movement around the hip joint; they tend to maintain the leg in a flexed position. Because of increased pressure on the femoral nerve, they may complain of paresthesia, hyperesthesia, or weakness of the quadriceps muscle. An iliopsoas bleed can be confused with a hemarthrosis of the hip (see box on Hip Joint Bleeds). Urgent ultrasonography or magnetic resonance imaging (MRI) examination is required to differentiate between the two conditions. Iliopsoas muscle bleeds need prolonged treatment with factor concentrates, as well as immobilization and physical therapy. This may necessitate hospitalization (see box on Hemophilic Pseudotumors).[8]

Hemarthrosis

Bleeding into joints accounts for about 75% of all bleeding events in hemophilia and is the hallmark of hemophilia. Although any joints may be involved, the most commonly involved are the ankles, knees, and elbows. These three joints are therefore referred to as *index joints*. Less commonly involved joints are the shoulders, hips, and wrists. The least involved are the joints in the hands and feet.

There is significant variability in the time when children with severe hemophilia experience their first joint bleed. Although the median age to experience the first joint bleed is around 1.8 years, some children experience this within the first year of life (as they begin to ambulate) and others not until their fourth, fifth, or sixth years of life.[9] Hemarthroses become more common as children age if they are not placed on prophylactic therapy. Hemarthrosis can be either spontaneous or trauma related; the trauma may be imperceptible. Mild trauma may even occur while the child is asleep, causing the child to wake up with joint pain and swelling. The onset of a hemarthrosis is often signaled by a feeling of warmth and tingling in the joint. This may last for several hours before increasing pain and limitation of joint movement set in. In patients with severe hemophilia, bleeding into the joint will continue until the patient receives hemostatic therapy or the pressure within the joint increases to the point of causing occlusion of bleeding vessels and bleeding cessation. In the later scenario, the pain in the joint may be excruciating. In patients with moderate or mild hemophilia, the bleeding may stop without the administration of hemostatic replacement but only after substantial bleeding has occurred. Consequently, joint bleeds should be treated as soon as possible to minimize the extent of bleeding and reduce the risk of long-term disabling sequelae.

Blood in a joint leads to joint damage through at least three mechanisms: iron toxicity, inflammation, and mechanical distension of the joint. Repeated joint bleeds may result in inflammation and hyperplasia of the synovial tissue within the joint (a situation referred to as *synovitis*).[10] Synovitis is the first step toward the development of hemophilic arthropathy. Any joint that undergoes repeated bleeds is referred to as a *target joint*. The strict definition of a target joint is still under discussion, but in general, most clinicians tend to accept that a joint that bleeds three or four times in a 6-month period qualifies as a target joint. A target joint is a manifestation of synovitis, and if not managed with long-term prophylaxis, such a joint will continue to bleed and will ultimately become a chronically damaged, arthropathic joint. Early stage hemophilic arthropathy is characterized by synovial hyperplasia, extensive destruction of articular cartilage, progressive loss of joint space, cystic changes within the subchondral bone, osteoporosis, and atrophy of surrounding muscles. The final stage of hemophilic arthropathy is a deformed and dysfunctional joint. At this stage, joint bleeds become less frequent as synovial hypertrophy becomes less prominent.

Compartment Syndrome

A compartment syndrome arises when a bleed (usually trauma induced) occurs into a closed (encapsulated) space, such as the forearm or calf. The capsule restricts exit of blood, thereby raising the pressure within the compartment. This ultimately results in compression of blood vessels and obstruction of blood flow, leading to tissue ischemia and the potential for nerve and muscle damage. Compartment syndrome is characterized by severe pain and swelling, limb pallor, paresthesias, and reduced movement of the limb. Without treatment, a compartment syndrome may lead to permanent neuropathy, tissue necrosis, and even loss of the limb. This emergency condition requires urgent factor replacement and potentially surgical decompression (fasciotomy).

Hemophilic Pseudotumors

Pseudotumors are a rare but very problematic complication in hemophilia. The most common type of pseudotumor arises as a result of repeated hemorrhages into a muscle with insufficient resorption of blood between hemorrhages. Pseudotumors become walled-off cystic structures surrounded by a fibrous membrane. They may become multivacuolated over time, and parts may become calcified. These cystic lesions frequently expand into adjacent structures, leading to their destruction. Skeletal fractures and bony deformities may arise from such lesions. Another and rarer type of pseudotumor, generally only seen in adult patients, arises from within the bone itself and is often secondary to subperiosteal bleeding. This type of pseudotumor is typically observed in the long bones of the lower extremities and in the pelvis. Pseudotumors arising distally are more common in young children and most often occur in the hand. Pseudotumors may be associated with pain from rapid growth or nerve compression.

Pseudotumors are usually diagnosed by radiological means (ultrasonography or MRI). A pseudotumor may be misdiagnosed as a neoplasm (e.g., Ewing sarcoma or osteosarcoma) or as an infection (e.g., osteomyelitis or tuberculous abscess). Biopsy of such lesions is contraindicated because of the potential for significant bleeding or infection. Small pseudotumors, particularly distal ones or pseudotumors in patients with inhibitors, are often treated conservatively with aggressive clotting factor replacement along with immobilization of the affected limb.

Unfortunately, in some instances, factor replacement alone is insufficient, and complete surgical excision is needed. This carries potential morbidity and even mortality and should only be undertaken by skilled surgeons in conjunction with appropriate hemophilia specialists. Attempts have been made at embolization of such pseudotumors, and radiation therapy has been successfully used for treatment of small pseudotumors of the hand.

Determining the status of joints of patients with hemophilia at a given time or longitudinally over time necessitates both clinical and radiographic examinations. Over the past 10 to 20 years, clinical and radiographic scoring systems have been developed to objectively evaluate these findings (Table 137-6). Clinical scores are the most readily available, do not require expensive radiological equipment, and may be the most reflective of a patient's joint disability status. Plain radiographs are relatively inexpensive and widely available but are insensitive to the soft tissue changes seen in the early stages of joint disease and involve radiation exposure. MRI is the most sensitive to early joint (soft tissue) changes and does not expose patients to radiation but is limited by high cost, more limited availability, and the need for general anesthesia in very young children. Preliminary work is ongoing on the use of ultrasonography to evaluate acute and chronic changes in joints. Ultrasonography does not require sedation in young children; is much less expensive than MRI; and differentiates between synovium and hemosiderin, which is not always possible with MRI. However, ultrasonography also has limitations: (1) it is very operator dependent, and the interpretation of ultrasound findings can be subjective, and (2) some structures within a joint (e.g., cartilage) are not readily visualized.

Mucous Membrane Bleeding

Epistaxis is not a prominent feature of hemophilia, but it certainly can occur. Oral bleeding is, however, quite common in patients with hemophilia. Often, one of the first presentations of hemophilia is bleeding from the frenulum after trauma. Tongue bleeding, caused by a child biting the tongue, is also reasonably common. This can become an emergency, either because of significant blood loss or from tongue swelling to the point of airway obstruction. Excessive bleeding with loss of deciduous teeth and eruption of secondary dentition can occur but is not common in hemophilia. Fortunately, most bleeding from the mouth can be controlled with antifibrinolytic agents, such as tranexamic acid (Cyklokapron) or epsilon aminocaproic acid (Amicar). Factor replacement may be required for more serious cases. For dental surgery, particularly if it requires a nerve block, factor replacement or DDAVP (desmopressin) needs to be given to raise the factor level to at least 30% of normal.

Hematuria

In the past, hematuria was a reasonably common occurrence in patients with hemophilia. Hematuria may be associated with trauma but most often is spontaneous, episodic, and usually painless. Hematuria can rarely be caused by renal calculi because these are thought to be more common in males with hemophilia compared with the normal nonhemophilic male population. There is no consensus on how best to manage hematuria in patients with hemophilia, but in general, increased oral fluids along with bed rest are recommended. If, despite these measures, bleeding continues or is particularly severe, factor replacement should be given; the use of steroids to manage hematuria in patients with hemophilia has been reported, but there is no conclusive evidence that steroids provide any additional benefit. Fortunately, hematuria in patients with hemophilia is not associated with progressive loss of renal function, and as such, its natural history is probably benign.

The use of antifibrinolytic agents (tranexamic acid or epsilon aminocaproic acid) is contraindicated with hematuria because of the risk of ureteral obstruction by clots.

Gastrointestinal Bleeding

Gastrointestinal bleeding can occur in patients with hemophilia, particularly in adults, in whom it is often associated with the chronic use of nonsteroidal antiinflammatory drugs (NSAIDs) for hemophilic arthropathy. Another potential explanation for GI tract bleeding is esophageal varices in patients with portal hypertension secondary to long-standing hepatitis C. Such patients may present with massive life-threatening melena or hematemesis.

Neurologic Bleeding

Intracranial hemorrhage is the most dangerous hemorrhagic event in hemophilic patients. It is at present, along with HIV and hepatitis C, one of the three leading causes of death in persons with hemophilia. In both neonates and children with hemophilia, ICH is the leading cause of death. ICH is also one of the leading causes of morbidity (mental retardation, seizure disorders, and motor dysfunction) in children with hemophilia.[11] The incidence of ICH is highest in neonates and is associated with the birthing process, particularly with a traumatic vaginal delivery. ICH is also seen in young children with severe hemophilia, particularly in those who are not on prophylaxis or have an inhibitor. In older adults, ICH again becomes more common, particularly in patients with coexisting HIV or hepatitis C. In such patients, mild to moderate thrombocytopenia is frequently seen either as a result of portal hypertension–induced splenomegaly or from HIV-associated immune thrombocytopenia. The combination of thrombocytopenia together with hemophilia increases the risk of CNS bleeding. ICH is rare in patients with mild or moderate hemophilia.

Most cases of ICH occur after trauma, but the trauma may be quite trivial, making the ICH appear to be spontaneous in nature. Patients with ICH usually present with neurologic symptoms soon after trauma, but bleeding may be delayed for several days or weeks. Typical neurologic symptoms suggestive of an ICH include drowsiness, loss of consciousness, seizures, headache, and vomiting. Any of these symptoms should alert the clinician to the potential for an ICH. In these circumstances, any person with hemophilia who has neurologic symptoms or signs should be presumed to have an ICH and should be immediately given a bolus of an appropriate factor concentrate to raise the patient's factor level to about 100%. This should always be done before any diagnostic procedure (e.g., computed tomography or MRI) to confirm the diagnosis of ICH. If an ICH is present, in addition to appropriate factor replacement, patients should be hospitalized for 10 to 14 days during which time they should be maintained on factor concentrate (by continuous infusion or frequent bolus infusions) to maintain a factor level over 100% at all times.

Lumbar punctures, which are almost never necessary in patients with hemophilia, and neurosurgical intervention, can safely be performed provided that 100% factor correction is achieved.

Intracranial bleeding may be subdural, epidural, subarachnoid, or intracerebral. Intraspinal (usually epidural) bleeding is rare, but when it occurs, can cause spinal cord compression.

Surgery and Bleeding

With the exception of circumcision in neonates, excessive bleeding is almost inevitable in patients with severe or moderate hemophilia who undergo surgery without adequate treatment with hemostatic agents. The bleeding can be acute or can be delayed for several hours or days. In addition to bleeding, surgery in such patients is characterized by poor wound healing as a result of poor clot formation along with prolonged bleeding and subsequent infection at the wound site. With appropriate management (factor replacement with or without other adjunctive hemostatic agents), intra- and postoperative hemorrhages can be prevented. With attention to the management of hemostasis, surgery can be performed safely in patients with hemophilia. Ideally, a multidisciplinary team is required to undertake surgery in a safe manner; physicians with expertise in the management of hemophilia patients should always be involved. Some surgeries might need to be adapted for patients with hemophilia (e.g., tissue cardiac valves are preferable to mechanical cardiac valves because of the relative contraindications of anticoagulant drugs in hemophilia).

CLINICAL MANAGEMENT OF HEMOPHILIA

As a lifelong, expensive, and disabling illness, the management of patients with hemophilia is complex and ideally best undertaken through comprehensive care in hemophilia treatment centers with multidisciplinary teams of health professionals. These teams should include a physician (usually a hematologist) with specialist training in hemophilia, a dedicated nurse, a physical therapist, and a social worker. Additional members that should be available for consultation include an orthopedic surgeon, a dentist, a genetic counselor, an obstetrician/gynecologist, a psychologist, a rheumatologist, a urologist, and (increasingly, for the management of elderly persons with hemophilia) a cardiologist. Fortunately, the role of the orthopedic surgeon in the management of hemophilia has been reduced in countries where prophylactic therapy can be provided.

Over the course of a lifetime, a patient and his family will experience numerous issues related to hemophilia. Significant psychological sequelae ensue for both affected children and their families. These children may be overprotected, and this may result in their experiencing difficulties in adjusting to the school environment and to society in general as they age. Hemophilia impacts children's school experience and what sports and recreational activities they are allowed to undertake. Some studies have shown lower academic performance and behavioral and emotional problems in school-aged children.[12] There may be multifactorial causes for this, including potentially silent ICH. These children may grow up with resentment toward their peers and nonhemophilic siblings and may harbor suppressed anger about having the condition. Hemophilia can also impact vocational choices and opportunities for adults with hemophilia with established arthropathy. In addition to all of the psychological sequelae of hemophilia, unfortunate men with hemophilia who acquired HIV and hepatitis C also have to deal with the myriad emotional and social ramifications of these devastating infectious illnesses.

For the family of people with hemophilia, the child's mother may experience considerable guilt knowing that as a carrier she passed the hemophilic mutation to her son. This can contribute to marriage breakdown, although it has not been ascertained whether separations occur more frequently in the marriages of parents of children with hemophilia than those of parents of children without the condition. Clearly, persons with hemophilia and their families require significant education, counseling, and support throughout the individual's lifetime.

For society in general, hemophilia with or without HIV or hepatitis C has a substantial impact, mainly because of the high cost of care.

The key aspects of hemophilia management are preventive therapy, treatment of bleeds, and care of the complications of hemophilic bleeding.

Preventive Therapy

Preventing trauma does much to reduce bleeding frequency in persons with hemophilia. One of the strategies involved in bleed prevention is restricting the child from high-risk sports (e.g., ice hockey, American-style football, rugby, and martial arts). A number of other sports (e.g., soccer, basketball, baseball, and tennis) also entail a certain amount of risk but for the child's psychological well-being are usually permitted. Other sports considered to be relatively safe include cycling (with a protective helmet), running, and swimming. Ideally, persons with hemophilia should be encouraged to keep active throughout their lives because osteoporosis and obesity are growing problems in this population as a result of inactivity. All patients with severe and moderately severe hemophilia should be told to wear helmets for bicycle riding, rollerblading, skateboarding, and downhill skiing. There is controversy regarding the use of helmets (outside of sports) in very young children as they are learning to walk and are unsteady on their feet and prone to falling. Some clinics advocate that patients between the ages of 1 and 2.5 years with severe forms of hemophilia wear a helmet at all times, with the exception of when they are sleeping. Whether this policy reduces the incidence of ICH is not known. Advising families on the importance of good dental hygiene is important because good oral hygiene may prevent or reduce the need for dental procedures (extractions, root canals), which entail a risk of bleeding. Unfortunately, dental care, including regular cleaning by a dentist, is often not subsidized by society and as such may be an expensive undertaking for families.

Vaccinations

Children with hemophilia have normal immune systems and should receive all routine vaccines. In addition, they should receive hepatitis B vaccinations at a young age because they are at a slightly higher risk of exposure to hepatitis B virus throughout their lives through the use of blood products. Recombinant factor concentrates and currently available plasma-derived factor concentrates do not transmit hepatitis B. However, patients with hemophilia are at a higher risk of requiring a routine blood transfusion because of trauma-associated blood loss, and there is still a small risk of acquiring hepatitis B from blood transfusions. It is not clear whether patients with hemophilia should receive the hepatitis A vaccination. However, the US National Hemophilia Foundation's Medical and Scientific Advisory Council has recommended that all persons with hemophilia who are seronegative for hepatitis A should be immunized against hepatitis A.

For persons with hemophilia, all vaccines should be given with care using the smallest gauge needle possible (#25 or #27) and applying pressure to the injection site for about 5 minutes. Vaccinations should be given subcutaneously rather than intramuscularly. This is a matter of some debate, however, because the majority of carefully administered intramuscular injections can be given safely. Nevertheless, there is an increased risk of hematoma formation after intramuscular injections subcutaneously administered. Vaccinations appear to produce the same immune response as those given intramuscularly.[13] Even if the immune response is slightly lower, the enhanced safety of subcutaneous injections renders this the preferred route.

Avoidance of Aspirin and Other Medications

Persons with hemophilia already have a severe bleeding disorder, and this can be exacerbated by aspirin. NSAIDS may also interfere with platelet function and should be avoided if possible. cyclooxygenase-2 inhibitors have less of an effect on platelet function than traditional NSAIDS. For older persons with hemophilia with coexistent cardiovascular disease, aspirin, other antiplatelet agents, or anticoagulants may be indicated, but such patients require coordinated care by an experienced cardiologist and a hemophilia specialist (see box on Home Care).

Treatment of Bleeds

When a bleed occurs in a patient with hemophilia, its immediate treatment is required to halt further bleeding. Rapid treatment prevents expansion of the bleed, accelerates healing, and reduces the risk of permanent disability. The longer the delay in providing treatment, the more bleeding will ensue and, consequently, the longer it will take to completely resorb the blood. If joint bleeds are treated rapidly, this will minimize the damage to the joint. Muscle bleeds if treated quickly tend not to become very big and have much less likelihood of transforming into pseudotumors or of causing a compartment syndrome. Rapid treatment of an ICH may save the life of the patient and minimize morbidity. Treatment of bleeds generally consists of more than just hemostatic support (factor concentrates or DDAVP). For example, whereas epistaxis and oral bleeding benefit greatly from the use of antifibrinolytic therapy, rest and physiotherapy are important components of the treatment of joint bleeds (see section on hemarthroses).

Coagulation Factor Concentrates

One of the main components of treating bleeds in hemophilia is replacement of the missing coagulation factor to achieve hemostasis. Until the 1970s, this entailed the use of plasma or cryoprecipitate. Plasma contains small amounts of FVIII and FIX. Consequently, when plasma is used as the source of clotting factor replacement, large volumes are needed. Cryoprecipitate contains a higher concentration of FVIII and, in the past, was commonly used for hemophilia A treatment. However, neither plasma nor cryoprecipitate is virally inactivated. Consequently, both of these blood products carry a risk of viral transmission. This limitation, together with issues of volume and convenience, has rendered these products obsolete management of bleeding in persons with hemophilia.

Home Care

Hemophilic treatment is best administered in the patient's home. Having a patient or other caregiver able to administer factor allows for prompt treatment of bleeds and facilitates prophylaxis. Teaching patients and families how to administer clotting factor concentrate is labor intensive and usually falls to the dedicated hemophilia clinic nurse. It often takes a long time before families become skilled at factor delivery. Most boys with hemophilia older than the age of 3 years can be treated at home after the parents are taught how to administer factor. In some children, poor venous access precludes routine factor delivery; these children often require implantation of a CVAD such as a port-a-cath or creation of an AVF. The teaching of home care is complex. Good sterile technique is critical to avoid CVAD or AVF infections. Later in life, children can be taught how to self-administer factor through peripheral veins. This is generally done in children between the ages of 8 and 12 years of age.

Plasma-derived clotting factor concentrates became available in the 1970s. In the early 1980s, it became evident that these concentrates were contaminated with HIV and hepatitis C. Consequently, thousands of hemophilia patients worldwide were exposed to these devastating viral illnesses, and many died of AIDS or of complications of hepatitis C. Out of this tragedy came the development of safer factor concentrates—plasma-derived concentrates that were subjected to effective viral inactivation methods, including solvent detergent, pasteurization, vapor treatment, nanofiltration, and dry heating—as well as recombinant clotting factors. Currently administered plasma-derived clotting factor concentrates are not associated with HIV, hepatitis B, or hepatitis C seroconversion. In theory, there still is a small possibility of transmission of viruses and prions from plasma-derived concentrates. Plasma-derived concentrates are generally classified as high purity (containing only the desired factor and very little else) or intermediate purity (containing the desired factor but with other factors present). In the case of FVIII, intermediate-purity products generally contain vWF (e.g., Alphanate [Grifols], Humate [CSL-Behring], and Wilate [Octapharma]), and intermediate-purity FIX products are prothrombin complex concentrates (e.g., Beriplex [CSL Behring], Octaplex [Octapharma], and Proplex [Baxter]), which, in addition to FIX, contain factors II, VII, and X, as well as protein C and S. In general, PCCs are no longer used for the management of bleeding in patients with hemophilia B because of the increased risk of thrombosis. In the late 1980s, recombinant factor concentrates were developed. First-generation recombinant products were stabilized by the inclusion of albumin in the final product. Second-generation products no longer contained albumin in the reconstituted preparation but were still exposed to human plasma-derived albumin during the manufacturing process. Third-generation products have no exposure to human or animal proteins and are stabilized with sucrose. Currently, all but one of the recombinant FVIII concentrates are derived from a full-length (as opposed to B domain–deleted) cDNA construct.

Recombinant factor concentrates are usually more expensive than their plasma-derived counterparts, but they have generally supplanted plasma-derived concentrates for hemophilia treatment because of increased safety and small volume of infusion. There is currently only one licensed recombinant FIX concentrate, but there are several different brands of recombinant FVIII. All brands of recombinant FVIII exhibit similar efficacy and are associated with similar rates of inhibitor development. With this in mind, the choice of FVIII concentrate is increasingly influenced by cost. There has been, however, some controversy over the incidence of inhibitors with the use of plasma-derived versus recombinant products. Currently, an international randomized study is evaluating this issue.

All currently available plasma-derived and recombinant concentrates have similar pharmacokinetic properties. The average half-life of FVIII concentrates (either plasma derived or recombinant) appears to be approximately 12 hours with no difference between currently licensed FVIII concentrates. The mean half-life of FIX is approximately 24 hours. The clotting factor half-life is affected by a number of factors. In the case of FVIII, it appears to be affected by the patient's endogenous vWF level, which in turn is related to the ABO blood group. The FVIII half-life appears to be shorter in children.

The recovery of factor concentrate refers to the increase in factor level achieved immediately after infusion of a given amount of factor. With FVIII concentrates, administration of 1 U/kg of FVIII increases the FVIII level by 2%. Therefore, achievement of a FVIII level of 100% in an individual with severe hemophilia requires a dose of 50 U/kg. For FIX, which has a volume of distribution twice that of FVIII, 1 U/kg increases the FIX level by 1%. Recovery of recombinant FIX is less, and in general, 1 U/kg increases the FIX level by 0.8%. Children exhibit lower recoveries of clotting factor, and dosing by body surface area may be more appropriate.

The dose and duration of substitution therapy depend on the severity of the bleed or the extent of the surgery. Table 137-7 shows the desired factor levels for various types of bleeding events and surgeries. After the initial bolus of factor, repeat doses are often necessary. For major bleeds, such as an ICH, or for major surgeries, such

Table 137-7 Recommendations for Clotting Factor Replacement

Site of Bleed	Level Desired (%)	Hemophilia A (rFVIII) (U/kg)	Hemophilia B (rFIX) (U/kg)
Oral mucosa	>30	20	40
Epistaxis	>30	20	40
Joint or muscle	>50	30	50
GI	>50	30	50
GU	>50	50	75
CNS	>100	75	125
Trauma or surgery	>100	75	125

CNS, Central nervous system; *GI,* gastrointestinal; *GU,* genitourinary; *rFIX,* recombinant factor IX; *rFVIII,* recombinant factor VIII.

as joint replacement, 10 to 14 days of full factor replacement may be required, but for less severe bleeds, such as an uncomplicated hemarthrosis, two or three treatments will usually be sufficient. For minor bleeds or minor surgeries (e.g., dental extraction) only 1 to 3 days of factor is required. For patients who require factor for a number of days, in addition to the initial dose of factor, bolus infusions are generally required every 6 to 24 hours depending on the severity of the bleed or the surgery. For major surgery it is generally desirable to maintain the factor level greater than 50% at all times in the postoperative period. This can be done with bolus infusions given approximately every 8 to 12 hours. In general, after the first infusion aiming for 100% replacement, subsequent infusions can be given at half the initial dose every 8 to 12 hours. Because of variable pharmacokinetics, factor levels should be monitored. This avoids high factor levels, which might be prothrombotic, and represent an unnecessary expense, as well as low factor levels, which increase the risk of bleeding. In addition, monitoring helps detect development of inhibitors. Determining the factor level at trough every several days ensures that the patient is achieving a hemostatic level of replacement.

An alternative method for maintaining hemostasis is by continuous clotting factor infusion. Substantially less factor is required with this form of treatment, and the peaks and troughs of repeated bolus administration are avoided. In general, a FVIII infusion rate of 2 to 3 U/kg/hr is sufficient after the FVIII level is increased to 100% with a bolus infusion of 50 U/kg. Although there has been concern about inhibitor development with the use of continuous infusion therapy, evidence that their treatment method increases the risk is lacking.

A number of long-acting FIX concentrates are currently undergoing prospective clinical studies. These studies are reported to have half-lives that are three to five times longer than those of the currently licensed FIX recombinant concentrate. In contrast, long-acting FVIII concentrates appear to have half-lives that are only 1.5- to 2.0-fold longer.

Adjunctive Treatments

Desmopressin

In the mid-1970s, Mannucci and colleagues showed that DDAVP (1-deamino-8 D-arginine vasopressin, desmopressin, Ferring Pharmaceuticals, Langley, UK), a synthetic analogue of the natural antidiuretic hormone, vasopressin, raises circulating levels of vWF and FVIII:C.[17] DDAVP causes the release of endogenous vWF from the Weibel-Palade bodies in endothelial cells into the blood. How DDAVP mobilizes FVIII is not well understood, but the recent discovery of endothelial sources of FVIII may help to explain this phenomenon. DDAVP also increases platelet adhesiveness and shortens the bleeding time independent of its effect on raising FVIII:C and vWF levels. Because DDAVP is not a blood-derived product or a factor concentrate, it is free of both infectious complications and potential inhibitor development. Furthermore, it is much less costly than factor concentrates and has few, generally mild and transient adverse events (flushing, headache, mild tachycardia, and hypotension). DDAVP, however, has antidiuretic activity and thus carries a risk of hyponatremia and seizures, particularly if given to very young children or to those with excessive fluid intake. Because of concern about hyponatremia, many clinicians do not give DDAVP to children younger than 3 years of age and administer DDAVP only once daily unless patients are hospitalized and serum sodium levels and fluid intake are monitored. The effectiveness of DDAVP decreases with repeated administration (tachyphylaxis) because of exhaustion of vWF/FVIII stores. Therefore, DDAVP should not be given for more than 3 consecutive days.

Most patients with mild hemophilia respond to DDAVP with a tripling of their FVIII:C levels to 30% or greater. In patients with moderate hemophilia, DDAVP rarely increases FVIII:C levels into a hemostatically effective range. All individuals with mild hemophilia A should be assessed for DDAVP responsiveness to determine whether they will benefit from this synthetic product. This involves determining FVIII and vWF levels before and 1 and 4 hours after DDAVP administration.

DDAVP can be administered intravenously, subcutaneously, or intranasally. The usual dose for intravenous administration is 0.3 μg/kg given in 50 mL of normal saline over 30 minutes. Intranasally, the usual dose is 150 μg (1 nasal puff) for patients weighing less than 50 kg and 300 μg (1 nasal puff into each nostril) for patients weighing 50 kg or more. The maximum effect of DDAVP is achieved within 30 minutes when given intravenously and within 60 minutes when given intranasally. In general, the safest approach to avoid hyponatremia is to restrict fluids in patients receiving DDAVP and to administer only isotonic solutions such as normal saline.

Because DDAVP stimulates vWF release from endothelial cells, it may increase platelet adhesiveness. In patients with hemophilia with risk factors for coronary or cerebral arterial thrombosis, this may result in angina, myocardial infarction, or stroke. Consequently, DDAVP should be used with caution in elderly men with hemophilia. Because DDAVP also stimulates the release of tissue plasminogen activator, it may exacerbate bleeding. Consequently, DDAVP is often administered in conjunction with antifibrinolytic agents.

Antifibrinolytic Agents

Antifibrinolytic agents are useful in the management of bleeding from mucosal sites where there is high fibrinolytic potential (e.g., the oropharynx, nose, GI tract, and uterine-vaginal lining). In hemophilia, antifibrinolytic agents (e.g., tranexamic acid or epsilon aminocaproic acid) are generally used in the context of oral bleeding or dental surgery. Oral tranexamic acid should be started 24 hours before the scheduled procedure or can be given intravenously immediately before the procedure. The dose of tranexamic acid is 10 mg/kg every 8 hours when given intravenously or 25 mg/kg every 6 to 8 hours when given orally. Tranexamic acid is available in 500-mg tablets, which can be crushed and dissolved in liquids for administration to young children. The usual dosage is 75 mg/kg every 6 hours. In general, antifibrinolytic agents should be administered for 3 to 10 days after a bleeding episode or an invasive procedure. Longer durations of therapy are required for tonsillectomy–adenoidectomy in which bleeding often occurs about 7 days after the procedure when the eschar detaches. The major contraindication to the use of antifibrinolytic agents is hematuria.

Fibrin Sealants

Experience with fibrin sealants in patients with hemophilia is increasing. Fibrin sealants function both as local hemostatic agents and as promoters of wound healing. They are particularly useful for dental

procedures. Fibrin sealants have been used successfully to reduce bleeding with dental procedures, circumcision, and after excision of hemophilic pseudotumors.

Adjunctive and Alternative Management Strategies for Joint Bleeds

In the management of joint bleeds, appropriate hemostatic support is critical, but other important measures include appropriate joint rest, analgesia, and graduated physiotherapy. The application of rest, ice (for 20 minutes every 3-4 hours), compression, and elevation (RICE protocol) during the first 24 hours after a joint bleed can provide substantial benefits. The role of joint aspiration in the management of joint bleeds remains controversial, but the procedure is advocated by some groups for management of persistent pain in large-volume hemarthrosis or for exclusion of septic arthritis. Orthotics and physical therapy are of vital importance in the management of acute joint bleeds and in dealing with long-term joint damage in patients with hemophilia. Ankle guards and arch supports are useful for patients with ankle arthropathy to improve gait and weightbearing capacity. Shoe lifts can equalize the length of the lower extremities when there is a leg length discrepancy. Muscle strength training enhances the mechanics of joint movement and provides protection and stabilization of the joint.

Surgical Management of Joint Disease

Surgical approaches to manage the complications of joint bleeds include surgical or arthroscopic synovectomy, nonsurgical (chemical or radionucleotide) synovectomy, various arthrodesis procedures, and joint replacement.

An open surgical or arthroscopic synovectomy endeavors to remove the inflamed and thickened synovial tissue that is the source of bleeding within the joint. Although it may reduce the frequency of bleeding, it does not improve joint mobility and may even worsen it.

Radionucleotide synovectomy has largely replaced chemical synovectomy. This involves injection of a radioisotope (e.g., yttrium^{90}, chromic phosphate P^{32}) into the joint space to obliterate synovial tissue. Compared with surgical synovectomy, radionucleotide synovectomy is less invasive, necessitates a shorter period of hospitalization, and requires less clotting factor coverage. Consequently, the procedure is less costly than surgical synovectomy. Radionucleotide synovectomy is particularly useful for patients with inhibitors because there is a lower risk of bleeding. However, long-term safety data are lacking in hemophilia.

Arthrodesis (surgical joint fixation) is particularly useful for painful joints with greatly compromised mobility in which joint replacement is not easily undertaken (e.g., ankles).

Joint replacements (particularly of the knee and hip) are still commonly performed procedures in adult patients with hemophilia. The elbow, which is not amenable to arthrodesis or for the most part to joint replacement, is often the most difficult joint to manage in patients with hemophilia. It is likely that there will be less need for surgical procedures with the introduction of prophylaxis regimens beginning in early childhood (see box on Hip Joint Bleeds).

Hip Joint Bleeds

Hemorrhage into the hip joint is uncommon compared with other joints. However, the clinical features of hip bleeds are less distinctive than those of more exposed joints, and it is possible that the incidence of hip bleeding is underestimated. Patients with a hip bleed maintain the hip joint in a partially flexed position, the position of lowest pressure. This position is similar to that seen in patients with an iliopsoas muscle bleed, causing these entities to be confused.

The management of acute hemarthrosis of the hip joint is somewhat different from that of other joints because of the vascular anatomy of the hip joint, which renders the head of the femur vulnerable to ischemia in the context of a bleed, causing raised intraarticular pressure.

Pain in the hip joint region may be caused by a range of conditions (hip joint bleed, iliopsoas muscle bleed, bleeds of surrounding muscles, retroperitoneal bleed, and appendicitis). Consequently, without appropriate imaging, a hip joint bleed may be easily misdiagnosed. Ultrasonography remains the preferred modality for investigation of hip pain because plain radiographs lack sufficient sensitivity to detect a hip joint bleed. Persistent pain despite appropriate factor replacement may indicate impending avascular necrosis and urgent consideration for joint aspiration by an experienced interventionalist (using ultrasound guidance) or by a surgeon. Graded physiotherapy should be instituted when symptomatic improvement is observed. Follow-up imaging studies (MRI, bone scan, or both) should be considered for assessment of avascular necrosis.

Prophylactic Clotting Factor Replacement

Experience has shown that if treated solely on demand, patients with hemophilia will experience frequent bleeds and will, over time, develop disabling joint disease. Prophylaxis treatment regimens reduce bleeding and prevent or limit joint damage in patients with hemophilia. The longest experience with the use of prophylaxis comes from European centers in Sweden, The Netherlands, and Germany.[18] Based on numerous cohort studies, good evidence shows that patients with hemophilia who received prophylaxis experienced fewer bleeds and maintained better joint function than patients treated on demand. There are several different prophylaxis regimens distinguished by dose and frequency of factor administration. The full-dose prophylactic regimen, often referred to as the Malmo regimen, involves administration of 25 to 40 U/kg of FVIII every other day (minimum, 3 days/wk) for patients with hemophilia A and the same amount of FIX 2 days a week for those with hemophilia B. Less intense "intermediate-dose" prophylaxis regimens involve the administration of 15 to 25 U/kg two to three times a week, and low-dose prophylaxis regimens call for the administration of dosages of 10 to 15 U/kg given one or two times a week. Primary prophylaxis regimens are started at a very young age (usually 2 years of age or earlier) before joint disease has developed (generally, before or immediately after the first joint bleed) and are continued long term. Secondary prophylaxis includes continuous long-term prophylaxis started at a later age (after 2 years of age) or after more than one joint bleed has occurred. The term *prophylaxis* also encompasses short-term prophylaxis regimens given after surgery or an ICH.

Ample evidence shows that prophylaxis must be commenced early in life to prevent joint disease. In addition, comparisons of different starting prophylactic regimens have shown that patients can be started on less intensive prophylaxis regimens and gradually escalated to full-dose regimens. Although full-dose regimens prevent bleeds more effectively than intermediate- and low-dose schedules, they cost more and may not be feasible in less affluent countries. In these countries, intermediate- or low-dose prophylaxis regimens may be more affordable, and these still confer significant benefit.

Although prophylaxis has been used for years, a recent randomized study that compared primary full-dose prophylaxis with on-demand therapy in young children with severe hemophilia was the first to highlight the benefits of this approach. Patients given primary prophylaxis experienced 90% fewer bleeds and after only a few years already exhibited less joint damage than those treated on demand.[19] The benefits of prophylaxis include reduced hospitalization, less time lost from school or work, improved school performance, and a reduced need for orthopedic surgery. Because of these benefits, the World Health Organization, World Federation of Hemophilia,

and many other national hemophilia organizations have endorsed primary prophylaxis as the standard of care for children with severe hemophilia.

The approach to prophylaxis varies by center and country. In some centers and countries, all patients are given full-dose prophylaxis, but in others, prophylaxis is individualized based on the severity and frequency of bleeding episodes.[20]

Burdens of prophylaxis include the need for venous access and cost. Patients receiving full-dose prophylaxis often require central venous access devices (CVADs) or arteriovenous fistulas (AVFs) for repeated factor administration, and full-dose regimens in young children are threefold more expensive than on-demand therapy. However, the cost of on-demand therapy increases over time because when joint bleeds occur, the subsequent joint damage triggers more bleeding. The social costs of joint damage are high in terms of lost time at school or work and limitations in vocational opportunities for adults with arthropathy. Whereas the costs of treating patients on demand rise over time, the cost of prophylaxis may stabilize or decrease when adults become less active. Although most children in Europe and North America are on prophylactic regimens, prophylaxis is less routinely used in adults.

Although there has been concern that starting prophylaxis early in life may increase the risk of development of inhibitors, mounting evidence shows that early initiation of prophylaxis reduces inhibitor development.

Considerations for Treatment of Hemophilic Bleeding in Adults

Although there is now little doubt that regular prophylactic infusions of clotting factor concentrate are the treatment approach of choice for children and adolescents, the role of prophylaxis in adults remains unclear. Although it may seem intuitive to maintain prophylaxis throughout life, this strategy is expensive, and its benefits have not been formally evaluated. Furthermore, some evidence indicates that not all children on prophylaxis required continued therapy as adults. Until more data are available, each case should be dealt with on its individual merits.

When prophylactic therapy in adult patients with hemophilia is undertaken, it should be administered in a manner best suited to the individual needs of the patient. Thus some patients prefer to treat themselves with a small amount of clotting factor every day (e.g., 500 U of FVIII/daily), but others prefer a once- or twice-weekly regimen with additional infusions before high-risk activities, such as sports. Prophylaxis should be used in patients with a target joint into which repeated bleeding is documented. In this instance, prophylactic concentrate infusions at regular intervals (three times a week for FVIII and twice a week for FIX) should be initiated and continued for several months or longer.

If an on-demand regimen is used, patients must be carefully counseled. Treatment should be started as soon as possible after the first signs of bleeding and, if appropriate, adjunctive measures such as rest, ice, compression, or limb elevation should be used to hasten symptom control.

Gene Therapy for Hemophilia

Since the cloning of the FVIII and FIX genes in the early 1980s, hemophilia has been a leading candidate for the application of somatic cell gene transfer.

The rationale for gene therapy in hemophilia includes the following: small increments in FVIII or FIX levels have a significant clinical benefit; regulation of FVIII or FIX levels is not critical as long as they do not reach supraphysiologic levels for extended periods of time; the site of coagulation transgene expression need not be restricted as long as sufficient amounts of the protein reach the circulation; and small (genetically modified hemophilic mice) and large (spontaneously generated hemophilic dogs) animal models of hemophilia are available for preclinical evaluation of gene transfer approaches.

Modes of Transgene Delivery

A key component to any gene transfer strategy is the development of a delivery system that enables efficient transfer of the therapeutic transgene to the recipient cell type of choice. After 30 years of investigation, viral vectors remain the most effective means of achieving high-level gene transfer. Although efforts have been made to enhance the efficiency of nonviral delivery methods such as liposome encapsulation, various physicochemical conjugates, and hydrodynamic injection, all of these approaches have limitations that preclude their advancement into the clinic at this time.

Hemophilia gene transfer studies have used three main types of viral vector: adenovirus, adeno-associated virus (AAV), and several forms of retrovirus. Trials of adenoviral gene transfer have been successful in animal models of hemophilia, but the single hemophilia A patient treated with an adenoviral vector experienced significant hematologic toxicity, and no further clinical studies have been undertaken with this vector type. Thus, although adenoviral gene transfer is highly efficient, these vectors elicit a major innate immune response upon cell entry, and the proinflammatory consequences of this response remain a significant safety concern. Therefore, until the innate immune reactivity of adenoviral gene delivery has been mitigated, this vector system will not be used for the treatment of hemophilia.

The second viral vector approach that has shown promise in hemophilia is the retroviral system. Initial studies were performed with replication-defective gammaretroviral vectors, and one human clinical study in hemophilia A also used this vector system. The major problem with these vectors is the requirement for recipient cell replication to facilitate nuclear entry of the vector. Consequently, gene transfer with these vectors is limited to tissues in which a significant proportion of cells are cycling. In contrast, lentiviral vectors are equally capable of transducing both postmitotic and replicating cells. For this reason, most of the more recent studies of retroviral hemophilia gene transfer have used lentiviral vector protocols in which the vector construct is usually derived from elements of the human immunodeficiency virus. The other major difference between lentiviral gene delivery and gene transfer with other viral vectors is that lentiviruses integrate their genome into the recipient cell genome as a natural part of their life cycle. Although viral vectors do not possess the structural components to enable further rounds of viral replication, there is a risk of insertional mutagenesis that can trigger activation of adjacent oncogenes or inactivation of tumor suppressor loci. Studies performed in the past 5 years indicate that lentiviral integrations are not random but tend to cluster in transcribed regions of the genome and more often occur within introns and coding regions of genes rather than in the upstream regulatory regions where γ-retroviruses insert.

In 2012, the lead candidate for hemophilia gene transfer is AAV (Table 137-8). This is a small nonpathogenic human parvovirus with a small, single-stranded DNA genome of approximately 4.8 kb. Infection in humans, which for some serotypes of the virus is frequent, is not associated with any clinical disease. The various serotypes of AAV have distinct tissue tropisms, and thus by using the

Table 137-8 Features of Adeno-Associated Virus–Mediated Gene Therapy

- AAV is a nonpathogenic virus.
- AAV rarely integrates into the host genome.
- There are no immediate adverse effects after AAV delivery.
- Innate immune reactivity to AAV is minimal.
- Vector readministration can be achieved with different vector serotypes (different capsids).
- Cytotoxic T-cell responses to capsid protein presentation can limit the duration of expression.
- Transgene size is limited to ~5 kb.

AAV, Adeno-associated virus.

capsid sequence for a particular serotype, gene therapists can target specific tissues for transgene expression. As one example, AAV-8 has excellent hepatotropic properties and has been successfully used for liver transgene delivery and expression. Upon entry into recipient cells, AAV is maintained within the nucleus in the form of stable extrachromosomal concatemers, and only a small proportion of the virus integrates into the recipient genome. Wild-type AAV preferentially integrates preferentially into a site on chromosome 19, but the replication-defective AAV vectors appear to insert into sites of natural chromosomal breakages. One significant limitation to AAV vectors is their small packaging capacity. Transgenes larger than 5 kb limit the capacity for viral particle assembly, and although this is not a problem for FIX (cDNA ≈1.4 kb), even the B domain deleted forms of FVIII (cDNA of ≈4.7 kb) are not easily accommodated by this vector type.

Clinical Trials of Hemophilia Gene Therapy

By the end of 2011, approximately 55 patients with hemophilia had undergone clinical evaluation of gene transfer strategies.[21] An initial trial of ex vivo gene transfer for FIX was performed on two subjects in China in the 1990s. A FIX gammaretroviral vector was used to transduce autologous skin-derived fibroblasts before reimplantation. No significant increases in FIX levels were observed. Since then, one patient has been treated with an intravenous FVIII adenoviral vector; a plasmid vector was used as a second ex vivo approach in which autologous fibroblasts were implanted into the omentum, and a small cohort of patients with hemophilia was treated with intravenous FVIII gammaretrovirus. Aside from the transient thrombocytopenia associated with adenoviral vector infusion, there were no adverse events, but none of those approaches increased FVIII or FIX levels beyond a few days, and even then, levels were in the 1% to 4% range.

In contrast, the AAV trials of gene transfer have shown evidence of therapeutic efficacy. There have now been three AAV FIX trials, the first into skeletal muscle and the latter two into liver. Both of the liver-directed trials, the first using hepatic artery delivery of AAV2 and the second systemic intravenous delivery of AAV8, have resulted in longer term expression of FIX at therapeutically relevant levels (between 2% and 10%) in some patients. Indeed, in the most recent AAV8 liver trial, the FIX levels have persisted beyond 5 months. Nevertheless, challenges persist. Most significant has been the recipient immune response against the vector capsid. This cytotoxic T cell–mediated response has resulted in transient hepatotoxicity in several patients and a subsequent loss of transgene expression in one patient. This immune response may be mitigated by transient immunosuppression, and recent evidence from the AAV8 trial suggests that a brief course of prednisone may be sufficient to minimize the hepatotoxicity. Of note, none of these patients has had an anti-FIX immune response.

The future for hemophilia gene therapy is promising. After 2 decades of excellent progress in preclinical studies, there is now realistic hope that clinical success will be achievable, at least for FIX gene therapy. Although AAV vector production will need to be scaled up and methods to limit the antivector immune response remain to be optimized, larger cohort studies are now possible. FVIII gene transfer may not be far behind, but the AAV packaging limitation and the inherent increased immunogenicity of FVIII are obstacles that need to be overcome (Table 137-9).

Complications of Treatment

Until the mid-1970s, the biggest impediment to the management of patients with hemophilia was the lack of readily administered treatment, which virtually guaranteed that patients with severe hemophilia would develop hemophilic arthropathy, and many would die of bleeding, including ICH. By the 1980s, treatments were available, and prophylaxis programs were initiated in many countries. Unfortunately, the 1980s was the era of HIV and hepatitis C, and most patients with hemophilia treated before 1985 were infected with both, with smaller numbers also infected with hepatitis A and B. Many of these patients have died. This tragedy prompted widespread implementation of blood donor screening programs and viral inactivation processes and accelerated the development of recombinant clotting factor concentrates.

The management of HIV since the 1980s has undergone tremendous advances. Currently, patients infected with HIV who receive highly active antiretroviral therapy (HAART) live almost normal life spans. Infection with hepatitis C is more problematic, resulting in chronic disease in approximately 60% of infected subjects. A combination of interferon and ribavirin has been used with good results in patients with certain hepatitis C genotypes 2 and 3 and less satisfactory results in those with genotype 1.

However, there are still patients developing the long-term complications of chronic hepatic infection, including an incidence of hepatocellular carcinoma. Co-infection with HIV and alcohol use with hepatitis C make the development of these liver complications more common. There are now several new-generation anti-HCV therapies reaching the clinic, and this may facilitate the cure of increasing numbers of infected patients with hemophilia. In the meantime, all noninfected persons with hemophilia routinely receive hepatitis A and B vaccination.

Other Comorbidities in Patients With Hemophilia

With the progressive improvements to hemophilia care, persons with hemophilia are living longer, and the morbidities associated with aging are now complicating the clinical management of hemophilia. Although patients with hemophilia are somewhat protected from atherothrombotic events, there are increasing numbers of older patients with coronary artery disease. This problem is necessitating the development of new guidelines to safely introduce antiplatelet regimens for secondary prevention or for primary prevention in those undergoing percutaneous coronary interventions.

Table 137-10 Factors Associated With Successful Immune Tolerance Induction for Patients With Hemophilia A and Factor VIII Inhibitors

	Known or Probable Factors	Possible or Hypothesized Factors
Patient-related factors	Low Bethesda titer (<5 or 10 BU) at start of ITI Low historical peak Bethesda titer (<50 or 200 BU)	Low peak Bethesda titer during ITI Patient ethnicity Young age
Treatment-related factors	Short interval between inhibitor diagnosis and start of ITI	High FVIII dose (for patients with high Bethesda titers only) vWF-containing FVIII concentrate used for ITI

BU, Bethesda unit; *FVIII,* factor VIII; *ITI,* immune tolerance induction; *vWF,* von Willebrand factor.

Current Limitations to Treatment for Hemophilia

Currently, the biggest impediments in the management of patients with hemophilia are cost, inhibitor development, and the need for CVADs.

1. **Cost:** Worldwide, cost is the major issue. Currently available factor concentrates, particularly recombinant factor concentrates, are very expensive, and prophylaxis regimens can cost as much as $300,000 per patient per year.
2. **Inhibitor development:** Management of patients with inhibitors remains a challenge. Although inhibitor development is more common in patients with hemophilia A (particularly severe forms), patients with hemophilia B are difficult to manage because they often develop anaphylaxis and nephrotic syndrome. Although the genetic and environmental risk factors for inhibitor development are increasingly well understood, our capacity to prevent inhibitor development is limited.
3. **CVADs:** These are useful for the management of young children with severe hemophilia. They are of particular benefit in children who develop inhibitors and require immune tolerance therapy (ITT). Most ITT regimens call for daily administration of factor, which is not feasible through repeated peripheral venipunctures. CVAD complications include infections and thrombosis. Catheter infections caused by skin organisms can produce considerable morbidity, and the CVAD often needs to be removed. In a meta-analysis of studies evaluating CVAD complications, Valentino and colleagues reported a 40% CVAD infection rate with a mean of one CVAD infection for every four patients with hemophilia with a CVAD in place for 1 year.

Thrombi associated with CVADs vary in significance from small fibrin sheaths to thrombi that occlude large vessels and can lead to pulmonary embolism or death. Several studies have shown that radiographically proven CVAD associated thrombosis develops in up to 50% of patients with hemophilia with devices. Such thrombi may impair CVAD function, thereby necessitating their removal. Because of the complications associated with CVAD implantation, some institutions recommend arteriovenous fistulae (AVF) as an alternative. However, experience with AVF is still limited.

Immune Responses to Exogenous Factor VIII and Factor IX

Adverse immunologic responses to replacement products are a major complication for patients with hemophilia who have access to replacement factor concentrates. These responses occur because the infused factor contains foreign epitopes. However, not all patients develop an immune response to replacement; the reasons for this are unknown.

Immune responses include anaphylactic reactions and nonanaphylactic antibody-producing responses. The latter are classified according to their effects in vitro: whereas immunoglobulin G (IgG) antibodies that "inhibit" the coagulant function of the replacement factor are referred to as *inhibitors,* those that do not interfere with coagulant activity are called *nonneutralizing antibodies.* C*atalytic antibodies* directly hydrolyze the target protein.

Anaphylactic Reactions

Type I hypersensitivity reactions are rare in patients with hemophilia A but have been reported with infusion of either plasma-derived or recombinant FVIII concentrates. Rarely, there is evidence of IgE mediation, suggesting that in some cases, these reactions may reflect complement activation, immune complex formation, or other mechanisms.

Approximately 3% of patients with hemophilia B experience anaphylactic reactions to FIX products; these occur with equal frequency with plasma-derived and recombinant products. The median number of FIX exposure days at the time of anaphylactic reaction is 11.[22] These reactions often occur in patients who have FIX inhibitors and show evidence of IgE mediation. In some cases, transient IgG1 antibodies to FIX have been detected near the time of the allergic reaction. Because IgG1 antibodies can bind complement, this may point to an alternative mechanism for anaphylactic-type reactions without evidence of IgE mediation. Factors that may confer an increased risk for anaphylactic reactions to FIX include Hispanic race, personal or family history of other allergies, and severe hemophilia B (FIX:C <1%). Anaphylactic reactions appear to be predominantly associated with total deletions and nonsense mutations of *F9.*[23]

It is unclear why anaphylactic reactions are more common with FIX concentrates than with FVIII concentrates. It is possible that the extravascular distribution of FIX is more likely to provoke such a reaction. In addition, therapeutic doses of FIX contain much more protein than therapeutic doses of FVIII, which may trigger anaphylaxis. Total deletions of the *F9* gene may also include deletions of adjacent genes whose absence may predispose patients to anaphylaxis.

The acute management of anaphylaxis involves supportive care and the use of non–VIII or non–FIX-containing bypassing agents to treat bleeding. Desensitization by repeated administration of concentrate may be successful, particularly in patients with hemophilia B. Because of the timing of anaphylactic reactions in hemophilia B, it is recommended that the first 10 to 20 FIX treatments be given in a controlled setting.

Inhibitory Antibody Development

This important treatment-related complication is dealt with in detail in Chapter 138. The current chapter deals with selected issues concerning pathophysiologic mechanisms and inhibitor detection only.

Factor VIII Inhibitors: Pathophysiology

Factor VIII inhibitors in patients with hemophilia A are antibodies of the IgG isotype and are typically of the IgG4 subclass, although inhibitory antibodies of other subclasses are observed as well. Some evidence indicates that IgG4 antibodies are predominant in patients with high-titer inhibitors, but IgG1 antibodies are more abundant in patients with low-titer inhibitors. The predominance of IgG4 antibodies may be a consequence of prolonged exposure to exogenous FVIII because this phenomenon has been observed with repeated administration of other antigens.

Factor VIII epitopes for inhibitory antibodies have been identified in several locations in the FVIII molecule, such as in a site in the A2 domain that is involved in the function of the tenase complex, in the FIXa-binding site in the A3 domain, and in phospholipid-binding and vWF-binding sites in the C2 domain. The presence of these epitopes in areas of the FVIII molecule that have functional importance explains why antibodies to these epitopes have inhibitory activity (i.e., result in decreased coagulant activity of FVIII). In contrast, antibodies directed against the nonfunctional B domain do not appear to have inhibitory activity.

Inhibitors may be classified by the kinetics of their binding to FVIII. *Type I* inhibitors are characterized by a linear relationship between the antibody concentration and the logarithm of the residual FVIII activity; at high antibody concentrations, the inhibition of FVIII is near total. FVIII inhibitors in patients with congenital hemophilia A usually have type I kinetics. Inhibitors with *type II* kinetics do not display a linear relationship, and even high antibody concentrations do not result in complete inhibition of FVIII activity. Type II inhibitors are commonly autoantibodies seen in acquired hemophilia A, which is discussed later.

Inhibitors are produced when a FVIII-specific memory B cell is stimulated to differentiate into an anti-FVIII antibody secreting cell (plasma cell). This differentiation is dependent on binding of FVIII to the B-cell receptor, a membrane receptor in the immunoglobulin

superfamily of receptors, to the antigen for which it has specificity, and subsequent interaction with a CD4 positive helper T cell. The important role of helper T cells in the genesis of inhibitors is supported by diverse data: T-cell proliferation in response to FVIII is increased in hemophilia A patients who have inhibitors compared with those without. Blockade of CD3, a component of the T-cell receptor complex, has been shown to decrease inhibitor formation in vitro, as has stimulation of cytotoxic T-lymphocyte antigen 4 (CTLA-4), an inhibitory receptor involved in the downregulation of T-cell stimulation. Decrease of inhibitor titers, and even loss of inhibitors altogether, has been observed in hemophilia A patients with inhibitors who have human HIV infection, particularly those with very low counts of CD4-positive T cells. T-cell activation that effectively produces inhibitors requires costimulation from antigen-presenting cells (e.g., via the CD40/CD40 ligand pathway or the CD28/B7 pathway).

Some observations suggest that the stimulation of memory B cells can be accomplished without FVIII-specific helper T cells. B cells have been stimulated in vitro by T cells that are specific for antigens other than FVIII ("bystander antigens"). Furthermore, B cells can be stimulated by Toll-like receptor (TLR) agonists without T-cell help. The significance of these findings for human patients with hemophilia is not known.

In humans, FVIII epitopes for CD4 positive T cells have been identified in the A2, A3, and C2 domains.

Regulatory T cells (Tregs), which can suppress the activity of helper T cells, may have a role in determining whether an individual patient will be immunologically reactive or tolerant to FVIII. T-cell proliferation in response to FVIII stimulation has been observed in Treg-depleted peripheral blood from normal (nonhemophiliac) human subjects. Hemophilia A mice treated with rapamycin (a small molecule inhibitor of the serine kinase mammalian target of rapamycin [mTOR]) failed to develop inhibitors on exposure to FVIII and had increased number of Tregs compared with control mice that did develop inhibitors. Hemophilia A mice had lower inhibitor titers in response to FVIII with infusion of Tregs taken from wild-type mice than without. These observations are consistent with Tregs perhaps having an important role in determining the immunologic response of hemophilia A patients to exogenous FVIII and intolerance to FVIII in normal individuals.

Immunologic tolerance to FVIII in people without hemophilia A is not complete. Rarely, usually as a result of autoimmune disease, immunologic tolerance to FVIII fails, and autoantibodies to FVIII develop; this is known as *acquired hemophilia A.* Furthermore, antibodies to FVIII, detectable by enzyme-linked immunosorbent assay (ELISA) and Bethesda assay as well as other methods, can be found in the plasma of some individuals who do not have hemophilia A. T cells that are reactive to FVIII can also be found in normal individuals, although this reactivity is transient and less intense than for hemophilia A patients. The relevance of these observations for hemophilia A patients who have inhibitors is not known. Further understanding of the mechanisms that might prevent normal individuals from developing clinically important autoantibodies to FVIII, such as T-cell suppression by Tregs or neutralization of inhibitory antibodies by anti-idiotypic antibodies (antibodies to the antigen-binding region of the inhibitory antibody), might provide insight into inhibitors in hemophilia A patients.

Not all patients with hemophilia A who are exposed to replacement FVIII products develop inhibitors. The reasons for tolerance to FVIII in some patients are not clear, although some of the known risk factors for inhibitor development suggest possible explanations. For example, patients with large *F8* gene deletions and other mutations that cause an absence of any synthesized FVIII protein have an increased inhibitor risk, suggesting that patients who do have some synthesized protein may be tolerant to the epitopes that they do produce. However, the mechanism and site of this tolerance are not known. It has been hypothesized that some patients are exposed in utero, via maternal–fetal hemorrhage, to small quantities of maternal FVIII that induce immunologic tolerance in the fetus. However, there has been no observed association between inhibitor risk and intrauterine procedures such as amniocentesis, or with breastfeeding.

Another theory to explain the development of FVIII inhibitors in some patients is that of immunologic "danger signals": if a patient has exposure to FVIII at the same time as exposure to pathogen-associated antigens, such as infectious agents or vaccines, or to tissue injury, such as surgical injury or acute bleeds, this may induce an immunogenic, rather than a tolerogenic, immune response to the FVIII antigen. Although specific danger signals, for example molecular patterns that are agonists for TLRs or other receptors in the innate immune system have not yet been definitively identified in association with FVIII inhibitor development, some clinical data are consistent with the danger signal hypothesis.

Transient Inhibitors

Some FVIII inhibitors may disappear spontaneously without specific management. Inhibitors may ultimately prove to be transient despite continued on-demand FVIII exposure. This typically occurs with low titer inhibitors (<5 Bethesda units [BU]) but can occur with higher titer inhibitors as well (≤10 BU). Transient inhibitors are also possible in patients with hemophilia B, but this phenomenon is not well characterized.

Catalytic Antibodies

Catalytic FVIII antibodies have been described that are capable of direct proteolysis of the FVIII protein.[24] These antibodies occur in approximately 50% of patients with FVIII inhibitors but have not been observed to occur in patients without inhibitors. The proteolysis caused by catalytic antibodies is specific to FVIII, and proteolytic cleavage sites have been identified at basic amino acids in the A1, A2, B, A3, and C1 domains. The rate of proteolysis by these antibodies is positively correlated with Bethesda titer and appears to be much slower than rates of other activating or inactivating enzymatic reactions involving FVIII, such as activation by thrombin or inactivation by protein C. It is possible to measure the effect of catalytic antibodies on the coagulant activity of FVIII with the Nijmegen assay, although the incubation time must be prolonged for proteolysis to occur.

The clinical importance of catalytic antibodies is unclear. It has been speculated that proteolysis of FVIII may create or expose neoepitopes, resulting in the formation of new antibodies, but it is not known if this actually occurs. In an inhibitor-positive patient, it is unknown what fraction of total FVIII inhibition is caused by catalytic antibodies. Perhaps most importantly, the effect of catalytic antibodies on infused FVIII is unknown. It is possible that the proteolysis catalyzed by these antibodies occurs too slowly to inactivate FVIII given for acute bleeds; on the other hand, even a slow reaction, if it ultimately inactivates enough FVIII, might impair the effectiveness of FVIII given for prophylaxis. However, it may be that catalytic antibodies work too slowly to have any clinically important effect.

Factor IX Inhibitors: Pathophysiology

Hemophilia B is less common than hemophilia A, a smaller number of patients with hemophilia B have severe disease, and inhibitors are much less common in hemophilia B. As a result, much less is known about the basic science of FIX inhibitors than about FVIII inhibitors. There is, as previously described, a relationship between FIX inhibitors and anaphylaxis to FIX that generally does not occur with FVIII inhibitors.

Factor IX inhibitors are primarily antibodies of the IgG4 isotype, although some are of the IgG2 isotype.

Epitopes for FIX inhibitors have been identified in the γ-carboxyglutamic acid domain, which is involved in binding to phospholipid surfaces, the serine protease domain, and possibly in the activation peptide region, at which FIX is activated by activated factor XI. As is the case with inhibitory FVIII antibodies, the

specificity of these antibodies for epitopes in functionally important regions of the FIX molecule explains their ability to inhibit FIX's coagulant activity.

Because FIX inhibitors are antibodies of the IgG subclass, they are products of interaction between FIX-specific B cells and helper T cells, but this process is less well described than is the case for FVIII inhibitors. The roles of costimulatory molecules, immunoregulatory genes, and Tregs in FIX inhibitors have not been demonstrated.

Detection of Inhibitors and Inhibitor Titers

Inhibitors are detected using the Bethesda assay (Fig. 137-12). In this assay, the ability of patient plasma, which may contain an inhibitor, to inhibit the coagulant activity of FVIII or FIX is measured using the activated partial thromboplastin time (aPTT). Plasma containing normal amounts of FVIII or FIX is used to create a standard curve that relates aPTT to FVIII or FIX activity. Patient plasma is incubated with the normal plasma for 2 hours at 37° C, the aPTT is measured, and the residual coagulant factor activity is then calculated. As a control, normal plasma is diluted with buffer, FVIII or FIX deficient plasma, or a 4% albumin solution, and the aPTT and coagulant factor activity are determined and compared with the result from the sample containing patient plasma. One Bethesda unit is defined as the amount of antibody required to reduce, in 1 mL of plasma, the coagulant factor activity to 50% of the activity present without antibody (or by a factor of 2^{-1}). By extension, 2 BU of inhibitory activity will decrease coagulant activity to 25% (by a factor of 2^{-2}), 3 BU to 12.5% (by a factor of 2^{-3}), and so on. In general: Bethesda titer (in BU) = $-\log_2$ (fraction of residual coagulant factor activity) = $-\log_{10}$ (fraction of residual coagulant factor activity)/$\log_{10}2$.

The Nijmegen modification of the Bethesda titer differs from the "classical" Bethesda assay in two respects: the normal plasma used is buffered to a pH of 7.4 with imidazole, and the control mixture is made by diluting normal plasma with FVIII deficient plasma rather than buffer. The Nijmegen modification is known to be more specific in detecting low-titer inhibitors than the classical Bethesda assay (i.e., it results in fewer false-positive results) and so is now the preferred assay for inhibitor quantification.

The Bethesda assay is poorly reproducible, although this can be minimized by rigorous standardization of laboratory reagents and procedures. The Bethesda assay will not, by definition, detect non-neutralizing antibodies (i.e., those antibodies to FVIII or FIX that do not inhibit the coagulant function of these proteins).

Both neutralizing and non-neutralizing antibodies to FVIII or FIX may also be detected by ELISA. This assay can only detect and quantify the antibodies present and cannot determine their inhibitory activity. It is possible that novel immunoassays with increased sensitivity will enter clinical practice in the future, but the importance and rational use of such assays will need to be determined.

An inhibitor may be categorized according to its titer: a low titer inhibitor has a Bethesda assay of less than or equal to 5 BU, but a high titer inhibitor has a Bethesda assay of greater than 5 BU. Whereas a low-responding inhibitor is one that remains at a low titer despite repeated FVIII exposure, a high-responding inhibitor is one that has a high titer (>5 BU) at any time after FVIII exposure even if the inhibitor titer decreases or becomes undetectable afterward.

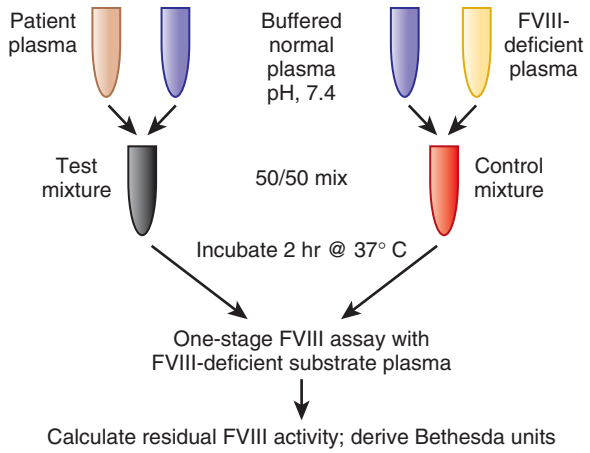

Figure 137-12 THE NIJMEGEN-MODIFIED BETHESDA ASSAY. This is the currently recommended methodology for quantifying anti–factor VIII (FVIII) inhibitory antibodies.

FUTURE DIRECTIONS

Already, in 2011, hemophilia represents a superb example of the application of molecular science to clinical benefit. Mutation-specific diagnosis is now being incorporated into the initial workup of many patients, and family counseling for kindreds with hemophilia has been dramatically enhanced by advances in the application of molecular genetic technology. In addition, use of the hemophilic mutation as a significant risk factor for inhibitor development is prompting clinicians to evaluate novel strategies to mitigate the likelihood of this treatment complication. As our ability to analyze the genome in far greater detail at greater speed and with reduced costs increases, we can look forward to an even greater potential for inhibitor risk definition.

The increasing use of recombinant factor concentrates worldwide is a strong indicator of our growing reliance on novel technologies to provide safe and effective therapies for hemophilia. In the next 5 to 10 years, we can look forward to a large number of additional innovations in the area of hemophilia treatment (Fig. 137-13). The first wave of novel products is aimed at extending the circulating half-life of the concentrates with the objective of reducing the frequency of replacement therapy. The two main approaches being used for this purpose are the conjugation of the clotting factor protein to hydrophilic polymers such as polyethylene glycol or the generation of recombinant fusion proteins using immunoglobulin or albumin as the fusion partner.

A second, more challenging approach to improving hemophilia therapy is to develop components of an improved intrinsic tenase complex. Currently, early phase investigations are exploring the

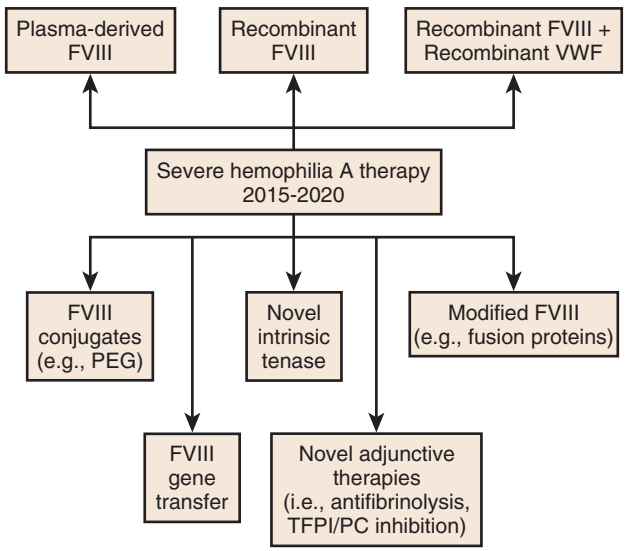

Figure 137-13 THE FUTURE OF HEMOPHILIA A TREATMENT. This figure speculates on the therapeutic options that may well face clinicians treating patients with hemophilia A within the next 5 to 10 years. *FVIII,* Factor VIII; *PC,* Protein C; *PEG,* polyethylene glycol; *TFPI,* tissue factor pathway inhibitor; *vWF,* von Willebrand factor.

potential of enhanced activity FIX variants and the development of FVIII mimetics that incorporate the various roles that FVIII plays as a "scaffold" protein in this membrane-bound complex.

Finally, various adjunctive strategies for hemophilia treatment are being pursued. These include inhibition of coagulation inhibitory proteins (tissue factor pathway inhibitor and protein C) with antibodies and nucleic acid strategies (siRNA) and the development of novel approaches to inhibit fibrinolysis.

Overall, the future for a more diverse array of hemophilia therapeutics seems highly promising. How each of these products will be used in individual patients will provide future hemophilia treaters with some interesting and ultimately gratifying challenges.

CHAPTER 138

INHIBITORS IN HEMOPHILIA A AND B

Guglielmo Mariani, Barbara A. Konkle, and Craig M. Kessler

With the availability of plasma-derived and recombinant replacement products safe from transmission of known infectious agents, the development of antibodies neutralizing factor VIII (FVIII) or FIX has become the major complication of hemophilia treatment.

The immune response to FVIII occurs and antibodies to FVIII can be detected in (1) healthy individuals, (2) patients suffering from an autoimmune disease, and (3) patients with factor VIII deficiency (hemophilia A). Clinically speaking, only those antibodies that affect the clotting activity, which are therefore termed *inhibitors,* are considered relevant because they render patients refractory to treatment. In hemophilias, inhibitors occur after factor replacement therapy with FVIII or factor IX concentrates. Patients with a severe deficiency (FVIII or FIX < 1% of normal) are particularly at risk.

Inhibitor formation in hemophilia was first reported in 1941.[1] A 44-year-old man with classic hemophilia had been treated numerous times with blood products, and his coagulation time subsequently became refractory to transfusions. The authors realized that transfusion may have caused this heretofore unknown complication and suggested that coagulation times should be checked after administration of blood products to monitor for the phenomenon. This report soon was followed by numerous cases[2-5] reporting the development of a substance that counteracted infused blood product components. The nature of the inhibitor was shown to be an IgG antibody of the IgG4 subclass.[6]

Alloantibody inhibitors arise much more frequently in patients with severe hemophilia A (15% to 20% with a range of 8% to 52%)[7] than in those with severe hemophilia B (≈1% to 3%). Their occurrence is associated with higher morbidity and mortality, increased cost of care, and more complicated treatment regimens.

HEMOPHILIA A

Epidemiology

It is curious that hemophilia A and B, which share an almost identical clinical phenotype, would have such a disparate incidence of alloantibody inhibitor development. The explanation may reside in the type of genetic mutation responsible for each disease. In hemophilia A, the severe phenotype most often is due to a null mutation, which is less common in hemophilia B. Null mutations result in complete absence of a translated protein product and are more likely to predispose to inhibitor formation. Also, FIX shares significant homology with the other vitamin K–dependent clotting factors, possibly protecting against inhibitor development.[8] Finally, it is hypothesized that because FIX is smaller and more abundant than FVIII, some FIX may cross the placenta, thereby inducing tolerance in the developing fetus.[8]

Among patients with severe hemophilia A, approximately 30% will develop an alloantibody inhibitor (compared with 3% of those with moderate hemophilia and 0.3% with mild hemophilia).[9] Inhibitor formation occurs early after initiation of replacement therapy. Data from prospective clinical trials of recombinant FVIII reveal that inhibitor development typically arises within a median of 8 to 10 "exposure days" (treatment days), but a wide range is not uncommon.[10] The risk for inhibitor development decreases inversely with increasing number of exposure days and is uncommon (≈2/1000 patient-years) after 150 exposure days.

There appears to be a bimodal distribution of inhibitor occurrence in severe hemophilia. The incidence peaks in early childhood in those younger than 5 years of age (64.3/1000 treatment-years), falls substantially between the ages of 10 and 49 years of age (5.3/1000 treatment-years), and rises again in older age (10.5/1000 treatment-years).[11] This finding raises the possibility that there is a breakdown of tolerance with aging.[11] Furthermore, inhibitor formation has a negative impact on overall mortality in severe hemophilia A patients, essentially canceling out the improved life expectancy realized in patients with severe hemophilia A population over the last 30 years.[12]

Genetic Factors

One of the most significant risk factors associated with the development of inhibitory alloantibodies in hemophilia A is the presence of a positive family history. The increased concordance rate of inhibitor occurrence in brother and twin pairs[13,14] provided the initial indication that genetic factors play a role in inhibitor development. Having a first-degree relative with an inhibitor raises the risk for inhibitor development threefold, resulting in an approximately 50% chance of inhibitor development compared with a control cohort in which there is a 15% risk.[13,14]

Patient ethnicity first emerged as a possible risk factor for inhibitor development in retrospective analyses of the prevalence of inhibitors in various racial cohorts included within large pooled populations of hemophiliacs.[14-17] African Americans and Latinos were observed to have a twofold higher rate of inhibitor formation compared with whites. For instance, in the Malmö International Brother Study (MIBS), inhibitors were noted in 27.4% of white patients and in 55.6% of African Americans.[14] This same racial trend was subsequently appreciated in prospective analyses of inhibitor development in the initial recombinant FVIII concentrate safety and efficacy trials.[18]

One potential and provocative explanation for the increased propensity of African Americans with hemophilia to produce FVIII relative to immunoreactivity is a mismatch between the host endogenous wild-type FVIII haplotype polymorphisms found only in blacks (H3, H4, and H5) and their exposure to the exogenous FVIII polymorphisms found in the commercially available brands of recombinant FVIII concentrates (either H1 or H2) used for replacement therapy. The risk for alloantibody inhibitor development is significantly higher among African Americans with haplotypes H3 or H4 than it is in those with the H1 or H2 haplotype (odds ratio [OR] of 3.4). These observations await confirmation in larger studies.[19]

Emerging data consistently indicate that certain FVIII mutations producing phenotypically severe hemophilia A[7,8] are strong predictors of inhibitor development.[20-22] Three general categories of mutations in FVIII place a patient at "high risk" for inhibitor formation: (a) inversions of intron 22 (intrachromosomal recombinations), (b) large deletions affecting more than one domain, and (c) nonsense mutations involving the light chain (the risk for inhibitor formation is twofold higher with light chain mutations than with heavy chain

mutations).[7,20] All of these mutations either eliminate FVIII protein altogether or alter the molecular conformation of the FVIII protein in such a way that innate immune tolerance cannot be achieved during fetal development. Consequently, the immune system recognizes exogenously administered native FVIII protein as "foreign."[21] The "low-risk" FVIII mutations consist of small gene deletions/insertions, missense mutations, and splice site mutations. It is postulated that some "nonfunctional" FVIII protein is produced with these FVIII gene mutations, which may be sufficient to induce partial central immune tolerance.[20]

Even with genetic information, it is not possible to predict which patients are at highest risk for development of alloantibody inhibitors. Inhibitors in the high-risk category occur 7- to 10-fold more frequently for large deletions and nonsense mutations (pooled OR = 3.6; 95% confidence interval [CI] 2.3-5.7 and 1.4 CI 1.1-1.8, respectively)[20] (≈35%)[21] compared with those with intron 22 inversions. Furthermore, inhibitors occur less frequency with small FVIII gene deletions/insertions (≈7%)[21] or missense mutations (≈4%) (pooled OR 0.5 [95% CI 0.4-0.6] and 0.3, 95% CI 0.2-0.4, respectively).[20,21] Intron 22 inversions are associated with a lower inhibitor frequency than would be anticipated for a genotype, which produces no circulating FVIII protein. However, recent data suggest that some of these hemophiliacs may possess intrahepatocyte-endogenous FVIII protein fragments, which can induce partial immune tolerance.[20] There does not appear to be any relationship between the type of FVIII gene mutation and the relative risks for developing high titer versus low titer alloantibody FVIII inhibitors.[20]

Environmental Factors

Despite the strong FVIII genetic influences that underlie inhibitor formation, clinical observations indicate that various environmental or epigenetic pressures contribute to the development of alloantibody inhibitors. For example, within the MIBS cohort, there are discordant monozygotic twins (i.e., identical twin brothers with the same mutations) in which only one brother developed an inhibitor.[13] In addition, among families with high-risk gene mutations, only about 30% of siblings with severe hemophilia A due to the intron 22 inversion form inhibitors. Even with multidomain deletions, the highest estimated inhibitor risk only approaches 75%,[14] implying that other patients with the same mutation are somehow protected against inhibitor formation.

A concerted effort has been made to explore the importance of other genetic determinants in hemophilia A patients that may contribute to alloantibody inhibitor development. Of the immune response genes, the presence of a microsatellite polymorphism in the promoter region (134 base pair variant) of the interleukin (IL)-10 gene, which may lead to upregulated B-lymphocyte activity, has been associated with a 73% incidence of inhibitor formation (OR of 4.4). A G308A polymorphism in the promoter region of the tumor necrosis factor (TNF)-α gene (A/A genotype) has been associated with 72.7% inhibitors and an OR of 4.0. On the other hand, there is little consistent or robust evidence that polymorphisms of major histocompatibility complex (MHC) class II alleles or of other inflammatory cytokine genes contribute to alloantibody inhibitor development.[21-23]

Among possible environmental risk factors, the age at first treatment has been implicated as a major independent contributor for inhibitor development. Initial observations suggested that the earlier the first exposure to FVIII-containing products occurred, the greater the risk for alloantibody inhibitor formation.[23-26] Children treated before 6 months of age have a cumulative inhibitor incidence of 41% compared with a 12% incidence if initial exogenous FVIII exposure is delayed until after the first year of life. Results of a subsequent case-control study suggested that early age of first exposure to FVIII treatment reflected the severity of the hemophilia conveyed by the particular FVIII gene mutation. Thus more intense FVIII replacement and high-risk FVIII gene polymorphisms were more strongly associated with inhibitor formation than was age. In fact, there appeared to be a protective effect against the formation of inhibitors when children were started on primary FVIII prophylaxis regimens early in life.[27] The United Kingdom Haemophilia Centre Doctors' Organisation (UKHCDO) study reported that peak inhibitor formation occurs in children younger than 5 years of age.[11]

The method of FVIII infusion (continuous infusion versus bolus administration) and the clinical scenarios for FVIII replacement have also been examined for their contribution to inhibitor formation. Although administration of FVIII by continuous infusion has the advantage of requiring less factor replacement over time and avoids the peaks and troughs seen with bolus administration,[28] intense replacement of FVIII by continuous infusion was more likely to induce inhibitor development than bolus injections (57% versus 14%) in patients who were otherwise considered to be at low risk (i.e., mild hemophiliacs).[29,30] These results were gleaned from the retrospective examination of the medical records of 54 mild hemophiliacs, of whom only 7 had received FVIII by CI; a prospective study in a larger population remains to be conducted to confirm this finding. On the other hand, intensive FVIII replacement in the context of injury, surgery, or inflammation appears conducive to inhibitor formation. In the retrospective CANAL study (concerted action on neutralizing antibodies in severe hemophilia A) of previously untreated patients (PUPs), 65% of those whose first exposure to FVIII therapy was associated with surgery developed an allogeneic FVIII antibody inhibitor (relative risk, 3.7), compared with a 23% inhibitor incidence when first exposure was not related to a "danger signal" indication.[30]

Perhaps the most controversial "environmental" risk factor for alloantibody inhibitor development involves the type of FVIII concentrate replacement used by the patient (low- to intermediate-purity plasma-derived FVIII versus high-purity plasma-derived FVIII versus recombinant FVIII concentrates). After more than 20 years, the question of whether use of recombinant FVIII concentrates (highest purity) leads to a higher inhibitor incidence than the lower purity concentrates remains largely unresolved.[31,32] This debate originated with the prospective trials of first-generation recombinant FVIII concentrates in PUPs, which mandated frequent monitoring for inhibitor formation (at least every 3 months).[33,34] In the Kogenate trial, the total incidence of any inhibitor formation in patients with severe hemophilia A was 29.2% within a median of 9 exposure days.[35] A similar inhibitor incidence rate of 31.5% was found in a prospective trial of Recombinate.[36] Thus, when compared with the inhibitor incidence rate of approximately 10% reported in older retrospective studies, which employed low-purity plasma-derived FVIII concentrates and screened less frequently for inhibitors,[37] recombinant FVIII seemed to be significantly more immunogenic. Prospective monitoring of patients receiving high-purity plasma-derived FVIII concentrates revealed a similar inhibitor rate as seen in those given recombinant concentrates.[38]

A number of variables could potentially have contributed to these observations and thus attenuate their importance from the clinical perspective. The recombinant FVIII trials in PUPs were the first large prospective clinical trials of hemophilia treatment, so their comparison with results of anecdotal or retrospective case reports and case series is inappropriate.[30-35] These trials were also the first to employ routine and frequent prospective monitoring for inhibitor development. In prior studies, testing for inhibitors was done only when deemed clinically important. Continued analysis of the results of the recombinant FVIII trials showed that almost half (11/23) of the inhibitors in the Kogenate trial were transient in nature, decreasing the prevalence of inhibitors upon extended observation.[35] A similar pattern was observed in the Recombinate trial; alloantibodies disappeared in 14 of 22 study subjects who developed an inhibitor despite continued treatment, eventually reducing the prevalence rate to 11.1%.[36] The older studies likely missed these ephemeral inhibitors. A Dutch study suggested that although transient inhibitors may develop earlier during treatment with ultrapure plasma-derived and recombinant FVIII concentrates compared with lower-purity plasma products, the overall risk for inhibitor development is similar.[39] The debate continues with conflicting data in both

PUPs and previously treated patients.[40-42] The recent UKHCDO case-control study examined inhibitor occurrence over 25 years of observation and identified "high-intensity treatments" rather than the type of FVIII product as the main risk factor for inhibitor development.[43] Similarly, an analysis of pooled data from over 2900 hemophiliacs indicated that the duration of study observation and follow-up and testing frequency for inhibitor presence, but not the source or purity of concentrate, explained most of the differences in inhibitor development seen in earlier studies.[38]

Proposed causes of variable immunogenicity among FVIII products have included neoantigen formation during their manufacture and their content of von Willebrand factor (vWF) protein, which is present in low- and intermediate-purity plasma-derived products but absent in recombinant FVIII concentrates.[25] It has been suggested that vWF may interfere with FVIII-dendritic cell interactions, alter FVIII molecular conformation, or mask T- or B-lymphocyte epitopes. The former scenario has been illustrated by the fact that previously low immunogenic plasma-derived FVIII concentrates were rendered highly immunogenic after extra viral-attenuation steps were added to their manufacturing processes.[44-46] However, when recombinant FVIII products were administered to patients previously and extensively treated with lower-purity FVIII products, the rate of inhibitor formation was low, consistent with low immunogenicity in this setting (relative overall risk for inhibitors, 0.8; for high-titer inhibitors, 0.9; for plasma-derived products versus recombinant FVIII products, 1.0; for switching FVIII products, 1.1).[41,47] A large prospective, randomized study comparing the immunogenicity of vWF-containing concentrates with recombinant FVIII concentrates in PUPs and minimally treated patients is ongoing. Nonetheless, most experts believe that the risk for inhibitor formation with the various FVIII concentrates is similar.

Mild Hemophilia

For patients with mild or moderately severe hemophilia A, inhibitors appear to develop at a cumulative incidence of 3% to 13%, commonly after periods of intense FVIII replacement associated with surgery or inflammatory states.[48] Advanced age (>60 years) and the presence of a particular FVIII gene mutation (R539C) are other risk factors,[48-51] suggesting that the capacity for immune tolerance in these infrequently, if ever, treated individuals may be compromised with aging and that immune challenge with FVIII replacement should be avoided whenever possible by administration of desmopressin (DDAVP) to enhance endogenous FVIII activity levels.

Venous Access

A disturbingly high incidence of infections occurs in FVIII alloantibody inhibitor patients with central venous access catheter devices (CVAD), particularly those with external devices who are undergoing immune tolerance induction (ITI) (124 episodes in 41 patients).[52] This may be related to frequent catheter accessing for administration of replacement therapy. CVAD-associated infection did not seem to affect the ability to achieve tolerance.[52] The presence of CVADs per se does not appear to be associated with increased inhibitor formation.[43]

Other Factors

Other miscellaneous proposed environmental influences on inhibitor development, such as breastfeeding and receiving replacement therapy in the context of vaccination, remain to be confirmed as significant risk factors.

Pathobiology of FVIII Alloantibody Inhibitor Formation

Circulating antigens, provided by the exogenous FVIII contained in the replacement therapies administered to severe hemophiliacs, undergo initial endocytosis and subsequent proteolysis by antigen-presenting cells and digested peptides that bind to MHC II molecules for presentation to T-cell receptor on $CD4^+$ T lymphocytes.[53] Costimulation signals subsequently mediate differentiation of T-lymphocytes into either T_H1 or T_H2 subsets. T_H2 cells secrete IL-4, IL-5, and IL-10 cytokines, which promote the synthesis of non–complement-binding immunoglobulins, predominantly IgG4, by B lymphocytes.[53] This polyclonal antibody response can result in the inhibition of FVIII function via multiple mechanisms.[54]

The weak association between MHC II phenotypes and FVIII inhibitor formation is dependent on the availability of "risk" MHC class I/II alleles.[55,56] T-lymphocyte involvement in inhibitor formation is manifested by evidence of isotype switching and somatic hypermutation of the B cells.[57] There are several FVIII epitopes against which $CD4^+$ T cells react strongly.[57] In addition, non–FVIII-associated gene polymorphisms can exert a protective influence on inhibitor development—for example, the C→T single-nucleotide polymorphism (SNP) at position -318 in the promoter region of the gene encoding for cytotoxic T-lymphocyte–associated protein-4 (CTLA4).[58] This polymorphism "downregulates" the effects of the costimulatory signal of the B7-CD28 complex, which mediates T-cell immune responsiveness to infused FVIII. The MIBS study group reported an odds ratio of 0.3 for inhibitor formation among a cohort of severe hemophiliacs with the T allele SNP despite their high risk for inhibitors by virtue of FVIII intron 22 gene inversions.[58] MIBS also identified polymorphisms in the IL-10 cytokine gene that are associated with inhibitor formation in severe hemophiliacs.[59] In support of the polygenic nature of inhibitor formation, there is emerging evidence that the regulatory T cell (Treg) lymphocyte system downmodulates the immune reaction to FVIII and plays a role in ITI induction.[60]

FVIII exists as a heterodimer, with a heavy chain containing the A1, A2, and B domains connected to a light chain containing the A3, C1, and C2 domains (Fig. 138-1). Short intervening acidic regions (a1, a2, and a3) aid in FVIII binding to factor X and serve as important sites for FVIII proteolysis by thrombin and FXa.[61] By serving as a cofactor for FIX in the intrinsic tenase complex, FVIIIa aids in the conversion of FX to FXa, which together with factor Va forms the prothrombinase complex on the activated platelet surface. This complex then converts prothrombin to thrombin, which in turn amplifies the coagulation system (see Chapter 123).[62,63]

Normally, when FVIII is secreted, it is noncovalently bound to vWF via the light chain, particularly through interactions with the A3 and C2 domain.[63] Upon thrombin activation, FVIIIa dissociates from vWF and via the C2 domain, which is no longer bound by vWF, binds to phosphatidylserine on the platelet membrane.[64] Neutralizing alloantibody inhibitors can interrupt this process (see Fig. 138-1) by (a) preventing FVIII interaction with vWF, thereby significantly decreasing its circulating half-life, (b) impeding the release of FVIIIa from vWF after thrombin activation, (c) increasing the time for inactivation before association with the intrinsic tenase complex, and/or (d) preventing C2 domains from binding the phospholipid.[65-69]

Other FVIII alloantibody inhibitors interact with the A2 domain, predominantly at the Arg4844-Ile5085 epitope, and interrupt FVIIIa-FIXa interactions, thereby impairing intrinsic tenase activity.[70] Regions outside the A2 and C2 domains are minor epitopes for FVIII inhibitors; however, inhibitor binding to the A3 domain blocks the FVIIIa-FIXa interaction.[70] The inhibitors in most hemophilia A patients recognize multiple epitopes in both the A2 and C2 domains, in contrast to autoantibodies directed against FVIII, which target either the C2 or A2 domain but not both.[70] Although antibodies that target B domain epitopes have been reported, these do not neutralize FVIII coagulant activity.

Another mechanism of FVIII inhibition involves alloantibodies that catalyze the proteolysis of FVIII.[71,72] FVIII-hydrolyzing IgGs are detected in more than 50% of alloantibody inhibitor patients and functionally resemble serine proteases. In contrast to the A2, A3, and C2 epitope specificity of the classical alloantibody inhibitors in severe hemophilia A, IgG-mediated hydrolysis occurs evenly throughout the FVIII molecule with resultant loss of FVIII activity.[73]

Clinical Manifestations

The frequency and severity of bleeding complications do not necessarily increase when an alloantibody FVIII inhibitor develops in a severe hemophilia A patient. Similarly, no predictive relationship exists between the Bethesda unit (BU) titer and the severity of bleeding. Any person with hemophilia, regardless of severity, who is undergoing treatment and fails to respond to the FVIII dose that had previously been effective should be promptly evaluated for the development of an inhibitor.[74] Routine laboratory testing for the presence of an inhibitor is recommended before any major surgical procedure. A truncated pharmacokinetic study is also useful for inhibitor screening because even low-titer (<5 BU) asymptomatic inhibitors may be detected when less than 66% of the calculated incremental rise in FVIII activity is achieved within 30 minutes of administration of exogenous FVIII (i.e., decreased recovery). In general, patients with hemophilia A who have alloantibody FVIII inhibitors will experience more frequent hemarthroses, more severe and progressive arthropathy, and an overall reduced quality of life compared with noninhibitor patients.[75,76] Those with inhibitors have more hospital visits and absences from school or work, and they are more likely to require assistive devices, such as wheelchairs or crutches.[76] In the past, development of an inhibitor increased the mortality risk, but with current therapy the mortality rate is falling. However, the mortality rate for those with inhibitors still exceeds that for patients without an inhibitor.[77]

If patients with mild to moderately severe hemophilia A develop an alloantibody FVIII inhibitor, it usually occurs after a period of intense factor replacement. Genetic factors likely play a role as well. The clinical manifestations are the same as in severe hemophilia patients with inhibitors, including reduced recovery of FVIII activity after FVIII infusion. Thus a patient with mild disease may convert to a severe phenotype upon an inhibitor development and may present with spontaneous bleeding.

Laboratory Diagnosis

In 1975, the Bethesda assay was devised as a simple and reproducible method for determining antibody titer and quantifying the extent of its inhibitory/neutralizing capacity. The assay is based on the ability of patient plasma to inactivate FVIII in normal plasma. The result is expressed in BUs.[78] Patient plasma is serially diluted with normal plasma, incubated for 2 hours at 37° C, and residual FVIII activity is then measured using a one-stage assay. One BU correlates with patient FVIII activity of 50%. A standard curve is generated, and the

patient's plasma is diluted until FVIII activity is between 25% and 75%, the linear portion of the standard curve. The inhibitor units are read from the graph and multiplied by the reciprocal of the dilution factor to determine the BU in undiluted plasma (Fig. 138-2).

To improve the specificity and reliability of the Bethesda assay, two groups developed the Nijmegen modification of the Bethesda assay.[79] The Bethesda assay can yield false-positive results, usually evidenced as low-titer inhibitors, because of decreased FVIII activity as pH increases and protein concentration decreases. The Nijmegen modification made two important changes to the Bethesda assay. First, the normal plasma and control mixtures were buffered with imidazole to a pH of 7.4, which prevents the FVIII:C inactivation that can occur at higher pH. Second, the imidazole buffer used in the control mixture was replaced with plasma depleted of FVIII in order to yield similar protein concentrations (Fig. 138-3). These modifications are now recommended for diagnosis of inhibitors.[80]

Care is needed to ensure that isolated prolongations of the activated partial thromboplastin time (aPTT) are not misdiagnosed as lupus anticoagulants or vice versa. The key maneuver to distinguish one from the other is based on the results obtained when patient and control plasma are mixed, and the aPTT is determined immediately or after 2 hours incubation at 37° C. Whereas the aPTT results determined immediately and after 2 hours incubation are similar to lupus anticoagulants, inhibitors exert an exaggerated effect upon incubation. This is a critical issue because patients with lupus anticoagulants do not usually bleed, whereas the bleeding with FVIII alloantibody inhibitors may be profound. In some instances, lupus anticoagulants and FVIII inhibitor may coexist.

Based on the results of the inhibitor assay, a value less than 5 BU is considered a low-titer inhibitor. If the inhibitor titer fails to rise despite repeated challenges with clotting factor protein, the patient is termed a *low responder*. In contrast, a patient with an inhibitor titer greater than 5 BU is considered a *high responder*.[80]

External quality control assessments examining the reliability of clotting-based inhibitor testing (Bethesda and Nijmegen) have noted considerable interlaboratory variability that could influence patient management and may contribute to differences in the incidence of FVIII inhibitors reported in various clinical settings.[81]

ELISA[82] or fluorescence immunoassay-based[83] assays may complement the clotting assays because these techniques also detect nonneutralizing antibodies against FVIII. The clinical implications of antibody-epitope interactions are unclear. There may be discordance between the results of ELISA-based inhibitor assays, which reveal the presence of an alloantibody, and functional clot-based assays, which determine the neutralizing capacity of the alloantibody. Pharmacokinetic studies may be useful in patients with antibodies that are not overtly neutralizing in the Bethesda assay because these antibodies may influence the circulating half-life of infused FVIII.[84]

Monitoring for inhibitor development in previously untreated patients is of paramount importance, especially when starting treatment or prophylaxis regimens because inhibitor development occurs early in the course of treatment. Guidelines recommend screening PUPs every 5th exposure day up to the 20th exposure day, and then every 3 months until the 150th exposure day.[85] Repeat testing should be performed before any invasive procedure or elective operation.[85]

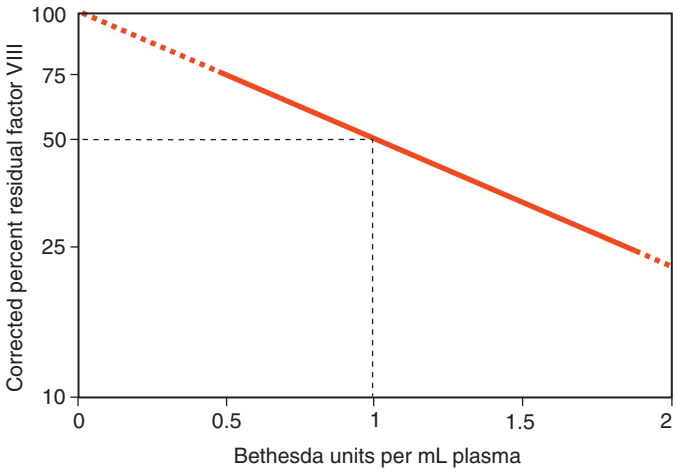

Figure 138-2 BETHESDA ASSAY FOR FACTOR VIII INHIBITOR QUANTITATION. Relationship between corrected residual factor VIII activity and Bethesda titer is shown. If the result is less than 25%, serial dilutions of the patient's plasma are tested until the result is between 25% and 75%. The result is multiplied by the dilution to assign the Bethesda titer. One Bethesda unit (BU) is defined by a corrected residual factor VIII of 50% in the assay *(dotted line). (From Konkle BA: Clinical approach to the bleeding patient. In Colman RW, Marder VJ, Clowes AW, et al, editors:* Hemostasis and thrombosis, *Philadelphia, 2006, Lippincott, Williams & Wilkins, p 1147.)*

Treatment

Patients with hemophilia should receive comprehensive and routine therapy at a hemophilia treatment center (HTC) of excellence, where expertise in the treatment of individuals with severe bleeding disorders and inhibitors is available. If emergency treatment or surgery is needed, patients should be transferred to the hemophilia treatment center as soon as possible and in a stabilized condition (see box on Treatment of Bleeding in a Patient With FVIII Deficiency and an Inhibitor). Typically, the HTC and its physicians serve as a community resource to help guide the care of complex inhibitor patients at other institutions when timely transport is not feasible due to active bleeding and hemodynamic instability.

Minor Bleeding Episodes

In established low-titer alloantibody FVIII inhibitor patients (consistently *less than* 5 BU after repeated challenges) or in patients with

Treatment of Bleeding in a Patient With FVIII Deficiency and an Inhibitor

Low Titer, Low Responder

Mild Bleeding

- Local and conservative measures, such as rest, ice, compression, and elevation
- If the patient is known to respond to DDAVP (i.e., mild hemophilia A), 0.3 μg/kg IV or 300 μg intranasal (150 μg per nostril; 150 μg for patients <50 kg) for minor bleeding or treatment before minor surgery
- Oral antifibrinolytic therapy (ε-aminocaproic acid or tranexamic acid) for mucosal bleeding
- FVIII dosing to raise the level to 50%
- Recombinant FVIIa (90 to 120 μg/kg, followed by 90 μg/kg every 2 to 3 hours)
- Activated prothrombin complex concentrates (50 to 100 units/kg, with maximum daily dose of 200 units/kg)
- Concurrent treatment with antifibrinolytics should be administered with caution

Life- or Limb-Threatening Bleeding

- FVIII dosing to maintain FVIII activity levels at 100%
- Recombinant FVIIa (270 μg/kg for one dose may be considered with caution versus 90 μg/kg every 2 to 3 hours)
- Activated prothrombin complex concentrates (100 units/kg, with maximum daily dose of 200 units/kg)
- Concurrent treatment with antifibrinolytics should be administered with caution

Low Titer, High Responder

Mild Bleeding

- Local and conservative measures, such as rest, ice, compression, and elevation
- If the patient is known to respond to DDAVP (i.e., mild hemophilia A), 0.3 μg/kg IV or 300 μg intranasal (150 μg for patients <50 kg) for minor bleeding or treatment before minor surgery
- Oral antifibrinolytic therapy (ε-aminocaproic acid or tranexamic acid) for mucosal bleeding
- Recombinant factor VIIa (270 μg/kg, bolus may be considered with caution versus 90 μg/kg every 2 to 3 hours)
- Activated prothrombin complex concentrates (100 units/kg, with a maximum daily dose of 200 units/kg, may induce anamnesis)

Life- or Limb-Threatening Bleeding

- FVIII in high doses to maintain levels of 100%
- Frequent monitoring for an anamnestic response, usually within 5 to 7 days
- After the anamnestic response develops:
 - Recombinant FVIIa (270 μg/kg, may be considered with caution versus 90 μg/kg every 2 to 3 hours)
 - Activated prothrombin complex concentrates (50 to 100 units/kg, with a maximum daily dose of 200 units/kg)

High Titer, High Responder

Mild Bleeding

- Local and conservative measures, such as rest, ice, compression, and elevation
- Oral antifibrinolytic therapy (ε-aminocaproic acid or tranexamic acid) for mucosal bleeding
- Recombinant FVIIa (270 μg/kg, should be considered with caution versus 90 μg/kg every 2 to 3 hours)
- Activated prothrombin complex concentrates (100 units/kg, with a maximum daily dose of 200 units/kg)
- Concurrent treatment with antifibrinolytics should be administered with caution

Life- or Limb-Threatening Bleeding

- Recombinant FVIIa (270 μg/kg, should be considered with caution versus 90 μg/kg IV every 2 to 3 hours)
- Activated prothrombin complex concentrates (100 units/kg, with a maximum daily dose of 200 units/kg)
- If available, immunoadsorption can be attempted to rapidly lower the inhibitor titer so as to allow use of FVIII

low-titer "transient inhibitors," larger doses of FVIII concentrate replacement can be given to overcome the neutralizing properties of the FVIII inhibitor. Such treatment may provide therapeutic levels of FVIII activity. The following equation approximates the dose necessary to overcome the neutralization effects of a low titer FVIII inhibitor:

$$\text{FVIII Replacement Loading Dose} = 2\,(\text{Body Weight in kg}\,[(80)(100-\text{Hematocrit})/100]/\text{BU})$$

FVIII activity levels should be determined after the infusion to ensure that adequate therapeutic levels are achieved and sustained. For invasive procedures, maintenance of FVIII level sufficient to maintain hemostasis adequately may require continuous infusion of replacement product. If a bolus dosing protocol is chosen, the treatment interval will need to be short, every 4 hours, to start with, followed by a schedule tailored to the aPTT or the FVIII level. Once the optimal bolus dose of FVIII replacement is established, home therapy may be possible.

High-titer FVIII alloantibody inhibitors are characterized by titers above 5 BU and by anamnestic responsiveness after repeated exposures to exogenous FVIII. Often, high-titer inhibitors may spontaneously fall below 5 BU, especially after prolonged lapses in FVIII reexposure. In this scenario, FVIII replacement should be avoided, if possible, so that anamnesis can be abated and the chances for successful immune tolerance induction and eradication of the inhibitor can be enhanced.[86] On the other hand, in urgent situations when "bypass" products are not available, low-titer inhibitor expression (<5 BU) may allow for effective use of FVIII concentrate replacement therapy, particularly in bleeds that are threatening to life or limb, because the anamnestic response will be delayed for several days. In these situations, administration of sufficient amounts of exogenous FVIII to overcome the immediate neutralization by the low-titer inhibitor will allow hemostasis to be achieved. Anamnestic rises in FVIII inhibitor titers have been observed after infusion of activated prothrombin complex concentrates to high-titer antibody patients, which are administered to bypass the inhibitor and to treat or prevent bleeding. These products contain a small amount of FVIII.[86-89]

Low-titer FVIII alloantibody inhibitors never rise above 5 BU and do not exhibit anamnestic increases after reexposure to exogenous FVIII. DDAVP administration may also be effective in selected patients with mild to moderately severe hemophilia complicated by an inhibitor (high or low titer). A DDAVP "challenge" should be undertaken before any intervention in order to assess the adequacy of incremental rises in FVIII activity in such patients.

Severe Bleeding Episodes

For patients who have an inhibitor titer less than 5 BU, administration of exogenous FVIII should be considered if FVIII levels can be

monitored closely. This approach provides the most specific and effective therapy; however, anamnesis can occur within a week in patients with a history of a high-titer inhibitor, and switching to a bypassing agent is indicated. Anamnesis may render subsequent use of exogenous FVIII therapy ineffective, so that even when exogenous FVIII replacement is anticipated to be effective in the short term, treatment should start with FVIIa or an activated prothrombin complex concentrate if prolonged periods of replacement therapy are necessary.

In the case of a severe bleed or a life-threatening emergency, the inhibitor titer should be determined as rapidly as possible, but treatment should not be delayed until the results are available. For patients with a known persistent high-titer antibody, prompt replacement treatment should consist of a bypass agent, either an activated prothrombin complex concentrate or recombinant FVIIa.

Surgery

Surgery in patients with hemophilia, especially those who have an inhibitor, requires the involvement of an entire facility experienced in the preoperative and postoperative care of such patients. Replacement therapy recommendations for surgical procedures are similar to those for hemorrhage. For known low responders, adequate hemostasis can be achieved with higher doses of FVIII. For the high-responding patient, activated prothrombin complex concentrate or FVIIa is most effective in the postoperative setting.[8-10]

Prothrombin Complex Concentrates

Prothrombin complex concentrates (PCCs) were designed for treatment of bleeding events associated with hemophilia B, congenital deficiencies of the other vitamin K–dependent clotting disorders, or with severe liver disease. PCCs were hypothesized to be useful to treat FVIII inhibitor-related bleeding because of their thrombogenic properties. Prepared from large pools of normal donor plasma, the PCCs contain the vitamin K–dependent clotting factors prothrombin, factor VII, factor IX, and factor X, as well as anticoagulant proteins C and S (action of the latter is unknown). Heparin or antithrombin is added to some preparations to limit activation of the coagulation factors during the manufacturing process and with administration. All PCCs undergo a viral inactivation process. In comparison with placebo, PCCs were shown to be partially effective in controlling approximately 50% of bleeding episodes in patients with FVIII alloantibody inhibitors, compared with 25% for product containing albumin alone.[90] A major caveat is that administration of PCCs to treat hemorrhage in hemophiliacs with inhibitors is *not* the treatment of choice and is justified *only* in the absence of more effective therapies.[90]

Activated Prothrombin Complex Concentrates and FVIIa

Activated prothrombin complex concentrates (APCCs) are PCCs that are "supercharged" by virtue of their partial "activation" during the manufacturing process with activated FVII credited for the maximum clotting potential. In a randomized, double-blind trial, an APCC showed significantly better control of bleeding events in severe hemophiliacs with FVIII alloantibody inhibitors than did PCCs ($P = 0.0085$); however, APCC was judged effective in only 64% of the episodes versus 52% effectiveness for PCC.[91] Uncontrolled clinical studies have shown that APCCs are effective in treating 81% to 93% of joint bleeds.[92,93] One should bear in mind, however, that APCCs are never as effective in inhibitor patients as is FVIII replacement in noninhibitor patients. Use of APCCs facilitates surgery in inhibitor patients and has been reported to be effective[93,94] and safe in large populations.[94]

APCC administration in a secondary prophylaxis regimen has also been deemed feasible, successful, and safe in reducing the frequency of bleeding events in severe hemophilia A patients with high-titer FVIII inhibitors. In the randomized, prospective, crossover Pro-FEIBA study, a statistically significant 62% reduction in all bleeding events was observed during the prophylaxis phase of the study (85 units/kg on 3 nonconsecutive days/week) compared with the on-demand period (85 units/kg every 6 to 12 hours).[95]

Use of PCCs and APCCs is hampered by the lack of laboratory tests to measure efficacy or to predict the potential for anamnesis (due to the presence of small amounts of FVIII) and the risk for precipitating thrombotic complications. The incidence of thrombosis is increased with regimens that exceed the recommended dosage and in patients at risk for thrombotic events, such as older individuals with coronary artery disease.

For acute bleeds, APCCs are administered at doses of 50 to 100 units/kg every 6 to 12 hours based on the clinical severity, with the maximum daily dose capped at 200 units/kg. This broader time frame allows for use at home for treatment of acute bleeds and for prophylaxis.

Recombinant FVIIa was purified from plasma and first used to treat a hemophilia A patient with an inhibitor in 1983.[96] Later, FVIIa produced by recombinant technology was found to be effective for preventing and treating acute bleeding. A randomized dose-finding trial determined that FVIIa effectively reversed 71% of joint and muscle bleeds within two to three doses, given every 2 to 3 hours.[97] Another prospective study established that 90 μg/kg FVIIa promoted adequate hemostasis during major surgical procedures, with an efficacy rate of 83% to 100%.[98]

Randomized prospective studies have directly compared the efficacy and safety of one dose of an APCC (factor eight inhibitor bypassing activity [FEIBA, Baxter], 85 to 90 international units/kg) with one to two doses of FVIIa (NovoSeven [Novo Nordisk Health Care AG] 90 to 105 μg/kg/dose) to treat acute joint bleeds. Although both products showed around 80% efficacy after 12 hours, equivalency was not shown at the 6-hour primary outcome point, but this was probably due to study design and underpowered cohorts.[99] When the primary outcome was the percentage of patients who required additional hemostatic replacement therapy 9 hours after initiation of treatment, significantly lower percentages of the 270 μg/kg (8.3%) and 3 × 90 μg/kg (9.1%) FVIIa treatment dose cohorts required rescue therapies compared with the aPCC treatment group (36.4%).[100]

Use of FVIIa is associated with some drawbacks, such as the lack of effective laboratory monitoring, very short half-life (≈2 to 3 hours, which necessitates frequent administration), potential for thrombotic events (more frequently observed in noninhibitor patients), and expense.

For acute bleeding events in inhibitor patients, debate exists as to whether the more convenient dosing regimen of a single large bolus dose of FVIIa (270 μg/kg) is as safe or efficacious as the multiple-dose regimen (90 μg/kg every 2 to 3 hours as recommended in the package insert). The initial concern was related to the thrombogenic potential of larger single doses, particularly in older individuals, since the large single-dose regimen was studied predominantly in children. In reality, a recent analysis of the FVIIa dosages used in FVIII inhibitor patients in the U.S.[101] ($n = 20{,}469$ doses, ranging from the 90 to 120 μg/kg FDA-recommended dose up to >270 μg/kg) revealed a very low incidence of thromboembolic complications (0.2%).[101] For serious life- and limb-threatening hemorrhages, a single 270 μg/kg bolus dose is recommended. Treatment of acute bleeds with FVIIa concentrate should be initiated as soon as possible because efficacy is inversely related to time to treatment. For surgery, some experts advise an initial dose of 120 μg/kg, followed by repeated 90 μg/kg doses every 2 to 3 hours.[102]

Parallel-Sequential Use of APCC and FVIIa Concentrates

For active inhibitor-associated bleeding episodes that are not totally responsive to treatment with either an APCC or rFVIIa concentrate alone, the administration of both products simultaneously or in an

alternating regimen (within 12 hours) has been anecdotally successful.[103-105] This combination is not recommended by the product manufacturers, and its clinical utility has not been studied in a scientifically valid manner. In vitro sequential "spiking" experiments[106] or ex vivo systematic infusion studies employing plasma specimens from inhibitor patients who have received these two types of bypassing agents alone, simultaneously, or in tandem[107] have demonstrated enhanced hemostasis for the combined approach. One study suggests that individualized bypass replacement therapy regimens can be designed for inhibitor patients based on the ex vivo responses observed in thromboelastogram tracings.[107] Although the efficacy of parallel treatment with bypassing agents may be excellent in most inhibitor related refractory bleeds, such regimens may increase the risk for thrombotic complications. A recent critical review of 49 inhibitor patients (9 acquired and 40 congenital), who received both bypassing agents in combined or alternating dosing regimens, reported 10 thromboembolic events, of which 1 was fatal.[108]

Prophylaxis With APCC and FVIIa

Prophylaxis regimens employing either APCC or rFVIIa to prevent acute and chronic arthropathy in inhibitor patients can be classified as primary (children awaiting ITI) or secondary (patients in whom ITI failed). Though not formally compared, prophylaxis with bypassing agents in inhibitor patients is not as efficacious as FVIII replacement in patients without an inhibitor. However, an accumulation of case reports and small clinical studies has suggested that prophylaxis with bypassing agents is safe and feasible in the subset of inhibitor patients with frequent bleeds, such as in target joints. The first prospective controlled study of prophylaxis in FVIII inhibitor patients[109] showed that a daily bolus dose 270 μg/kg of FVIIa is superior to a 90 μg/kg FVIIa dose in reducing the bleeding frequency (59% versus 45%) observed in the preprophylaxis period. An uncontrolled study[110] described equivalent efficacy and safety for FVIIa and APCC for prophylaxis in hemophilia A patients with inhibitors. Patients were placed on prophylaxis while awaiting initiation of immune tolerance induction. In this context the investigators favored the use of FVIIa to avoid potential anamnestic responses with APCC.[110] A recent prospective controlled trial demonstrated that a prophylaxis APCC regimen of 85 international units/kg three times/week reduced bleeding events by 62% in FVIII inhibitor patients, compared with an on-demand treatment regimen.[87]

Fibrinolytic Inhibitors

ε-Aminocaproic and tranexamic acid have long safety records and are commonly used in hemophilia patients, including those with inhibitors, as a sole treatment modality or as adjuncts to factor replacement for mucosal bleeding, dental procedures, and some orthopedic surgeries.[111]

For children, ε-aminocaproic acid can be administered orally at doses of 50 to 100 mg/kg every 6 hours. If used prior to a surgical intervention, the first dose should be given 4 hours before the start of the procedure. In adults, a loading dose of 4 to 5 g can be given initially, followed by similar or lower doses every 6 to 12 hours until bleeding is controlled (total suggested dose is 100 mg/kg/day). Fibrinolytic inhibitors are useful adjuncts for the treatment or prevention of bleeds treated with DDAVP in patients with low-titer inhibitors but should be administered cautiously when APCCs are used for high-titer inhibitors. Antifibrinolytic inhibitors are considered to be safe for use in conjunction with FVIIa.[88]

Immune Tolerance Therapy

The ultimate therapy for a patient with hemophilia complicated by a neutralizing inhibitory alloantibody is ITI. The goal of ITI is to eradicate the alloantibody. Successful ITI enables reinitiation of FVIII replacement for treatment of bleeding episodes and for prophylaxis. ITI is considered the best treatment option for hemophilia A patients with high-titer inhibitors.

The first successful implementation of ITI was accomplished in 1974 when a child with a high-titer inhibitor (>500 BU) required emergency reversal of a life-threatening bleed.[112,113] Very large doses of FVIII concentrate and a PCC were administered, and the hemorrhage was eventually controlled. A serendipitous finding was that the inhibitor titer decreased to almost 40 BU. This was the first documentation that high-dose FVIII administration could decrease inhibitor titers and provide proof of principle for the "Bonn protocol," which originally used high doses of FVIII (100 international units/kg) twice daily.[112,113] Bypass agents are administered as needed to treat acute bleeds that occur during ITI. This regimen is continued until the inhibitor disappears, which can take up to a maximum of 3 years.[113,114]

The Malmö ITI protocol was developed to induce rapid elimination of an alloantibody inhibitor in a patient with severe hemophilia B who required urgent orthopedic surgery.[115] Unique among the ITI regimens, the Malmö protocol uses concurrent immunomodulatory therapies in conjunction with large doses of clotting factor concentrate to lower the inhibitor level.[116,117]

As experience with ITI regimens increased, it became evident that low-dose FVIII replacement protocols also induce tolerance. Such regimens start with a dose of 25 international units/kg every other day, a 16- to 24-fold lower dose than those used in high-dose ITI protocols.[118,119]

Because of different ITI treatment protocols, a retrospective International Immune Tolerance Registry (IITR) was established in 1989. The registry eventually collected 314 alloantibody inhibitor patients (>94% high-titer) who underwent either low- or high-dose ITI treatment regimens.[120] The success rate ranged from 50% to 60% over time. Predictors of successful ITI included a low maximum inhibitor titer (85% success with ≤20 BU titer); low immediate pre-ITI BU (59% failure rate for >20 BU); higher FVIII dosage (86% success with ≥200 international units/kg/day); age of patient at initiation of ITI (60% failure for age >20 years); and shorter time interval between inhibitor detection and ITI initiation (>70% success for <5-year interval).[121,122] Although other registries yielded similar findings,[123-125] uncertainty remains as to the optimal total daily dose of FVIII, the use of concomitant immunosuppressive/immune-modulating agents, and the type of clotting factor replacement therapy (plasma-derived versus recombinant concentrates). Another important difference among protocols reported in the registries was the definition of success: stringent criteria (disappearance of the inhibitor, normal FVIII recovery and half-life) were not always accepted and therefore had an impact on the registry outcome evaluation. Although never formally proven, some believe that low- and/or intermediate-purity factor concentrates containing vWF may be more efficacious than recombinant FVIII for successful ITI.[126,127]

Other treatment-related elements that may influence ITI outcomes cannot be addressed in registries. These include the number of acute bleeds during ITI, use of CVADs, onset of infections during ITI, and use of plasma-derived PCCs or FVIIa to treat bleeds. Most of these questions were addressed in a randomized prospective multinational ITI trial that compared high- and low-dose ITI regimens, with the decision to use recombinant or a vWF-containing FVIII replacement product left to the discretion of the treating physician.[128,129] The results published to date have confirmed that ITI can eradicate alloantibody inhibitors in almost 70% of cases, even when very stringent outcome definitions are applied. Recombinant FVIII preparations were used in 90% of enrolled individuals, making it very unlikely that plasma-derived vWF-containing concentrates are superior to recombinant FVIII. The success rates with high-dose (200 international units/kg) and low-dose (50 international units/kg thrice/week) ITI regimens were similar; however, successful ITI was achieved 50% earlier with the high-dose regimen. The low-dose regimen was associated with an increased frequency of breakthrough bleeding events during ITI. This safety signal led to premature discontinuation of the study.

A high proportion of patients (41/99, 41%) with a CVAD developed access device infection, but this complication did not affect the likelihood of ITI success[129] and therefore should not reduce ITI use; however, it pinpoints the need for training and professional device nursing when long-term treatments are needed. Further prospective studies are needed to determine the optimal and most cost-effective dosing regimens for ITI.

A number of high-risk and/or ITI-relapsed patients have been treated with ritruximab, an anti-CD20 monoclonal antibody, with or without FVIII concentrate. Success rates have ranged from 33% to 57%,[130] suggesting that rituximab may be useful for salvage of patients with little or no response to conventional ITI regimens.

HEMOPHILIA B

The development of alloantibody inhibitors to FIX in severe hemophilia B follows the same general principles as in hemophilia A. Inhibitory alloantibodies may arise after administration of FIX-containing replacement products, and this phenomenon was appreciated very soon after hemophilia B was documented to be a separate entity from hemophilia A.[131] However, several distinct features in the epidemiology and treatment of FIX alloantibody inhibitors in severe hemophilia B deserve mention. These include (1) the lower incidence and prevalence of FIX alloantibody inhibitors; (2) the increased risk for developing anaphylaxis after administration of FIX-containing concentrates to FIX alloantibody inhibitor patients; (3) the risk for developing nephrotic syndrome after exposure to FIX-containing replacement products; and (4) the lower success rate of ITI therapy for eradication of FIX alloantibodies.[132,133]

Epidemiology

Patients with severe hemophilia B have a 10-fold lower risk for developing alloantibody inhibitors compared with severe hemophilia A patients (3% and 30%, respectively).[134] FIX gene mutations associated with a very low risk for inhibitor formation are single amino acid substitutions, whereas the risk for inhibitor development approaches 20% with more significant mutations, such as frameshift mutations, premature stop codons, large deletions, and splice site mutations.[134] Patients with hemophilia B who are at highest risk for development of inhibitors have a severe phenotype as a result of large gene deletions or other aberrations of the gene product, such as nonsense mutations. Although the latter mutations are found only in a small fraction of the hemophilia B population, they account for approximately 50% of the inhibitor population.[134]

Diagnosis

As in hemophilia A, an inhibitor should be suspected in hemophilia B when a patient ceases to respond to conventional replacement treatment. Given the possibility of anaphylaxis that may occur with initial treatment of bleeding episodes, patients with high-risk FIX gene mutations should be regularly screened for alloantibody inhibitors. The laboratory diagnosis for inhibitors in hemophilia B involves a modification of the same Bethesda assay used for quantification of FVIII inhibitors. In this case, FIX-deficient plasma is used instead of FVIII-deficient plasma.[135] In contrast to the FVIII inhibitor scenario, FIX inhibitors act rapidly to neutralize FIX in the normal plasma/patient plasma mixing studies; there is no time-dependent increase in the inhibitory expression of FIX alloantibodies over a 2-hour incubation at 37° C with either high- or low-titer FIX inhibitors.

Treatment

Treatment of hemophilia B in patients with FIX inhibitors mirrors that of hemophilia A complicated by FVIII alloantibody inhibitors. Both APCC and FVIIa are the key therapeutic modalities to reverse, control, and prevent bleeding regardless of whether it is spontaneous in nature or induced by trauma or surgery.[135] However, because APCC contains significant amounts of FIX, which may induce anamnesis, some experts prefer FVIIa.

Few treatment options exist for patients with FIX alloantibody inhibitors who have experienced allergic reactions to the FIX antigenic material found in plasma, PCC, APCC, high-purity plasma-derived FIX concentrate, or even in recombinant FIX concentrates. Anaphylaxis is, in fact, a major complication that can occur soon after the infusion of FIX-containing replacement therapies, manifesting as either a type II (dyspnea and hypoxia, and generalized hypersensitivity) or a type III (anaphylaxis and hypotension) allergic reaction. The rarity of anaphylactic complications in hemophilia B patients with FIX alloantibody inhibitors (only an estimated 35 cases have been reported) does not negate the seriousness of this complication.[132,136,137] In addition, this is likely an underreported and perhaps underrecognized event. The major risk factor for developing an anaphylactic reaction is the presence of a FIX gene null mutation, leading to an absence of circulating factor IX antigenic material.[138]

Because these severe reactions occur only after initiation of treatment, they have been observed only in children (median age 12 months), occurring at a median of 11 exposure days. The development of anaphylaxis occurs at the same time as the appearance of an inhibitor. A recent survey on the topic has shown that allergic reactions can be elicited with either recombinant or plasma-derived FIX concentrates at similar rates (3.9%).[139]

Because experience with anaphylaxis is limited by its low incidence, some general practice guidelines have been developed:

1. For newly diagnosed hemophilia B patients, especially those with high-risk FIX gene mutations, the initial FIX replacement treatments should be conducted in a medical facility where hemophilia expertise and resuscitation equipment are immediately available.[132]
2. Once an FIX alloantibody inhibitor has been documented, FVIIa is the treatment of choice for active bleeding and for prophylaxis against bleeding.
3. ITI is generally ineffective in these FIX alloantibody patients, although tolerance to FIX has been reported with progressively increasing doses of FIX (desensitization procedure) administered with hydrocortisone.[132,137]
4. FIX alloantibody formation may be complicated by nephrotic syndrome, especially in patients who previously experienced an allergic reaction to FIX replacement. The limited data available suggest that this syndrome is not the result of immune complex deposition, and it does not respond to corticosteroid treatment.[140,141] If nephrosis occurs, FIX doses should be reduced or treatment should be discontinued and FVIIa therapy should be used instead.[141]
5. In a few refractory cases with or without nephrosis, immune modulation (anti-CD20,[142,143] cyclosporine A[144] or mycophenolate mofetil[145]) has resulted in temporary immune tolerance to FIX.
6. Prophylaxis regimens with FVIIa (or APCC, if anaphylaxis and/or anamnesis is not an issue) may be useful in the context of high-titer FIX alloantibody inhibitors; however, additional large, long-term controlled trials are necessary before this approach becomes the standard of care.

CHAPTER 139

RARE COAGULATION FACTOR DEFICIENCIES

David Gailani and Anne T. Neff

Hemophilia A (factor VIII deficiency) and hemophilia B (factor IX deficiency) are the most common inherited deficiencies involving components of the plasma coagulation system (Fig. 139-1), with frequencies of 1:10,000 and 1:30,000 male births, respectively (Chapter 137). In comparison, frequencies of one in 500,000 to 2 million individuals are estimated for severe deficiency of other plasma coagulation factors, including fibrinogen; the protease zymogens prothrombin factors VII, X, XI, XII, and prekallikrein; the cofactors factor V and high-molecular-weight kininogen; and the transaminase factor XIII. These disorders are primarily autosomal recessive conditions, implying a carrier frequency of ≈1:1000, a value ≈10-fold higher than the mutant allele frequency for X-linked hemophilia A. Their rarity, therefore, is based on the fact that they are recessive conditions and not because of low allele frequencies. This is important to keep in mind, because partial (heterozygous) deficiencies of these proteins are relatively common and may be associated with mild bleeding symptoms in some cases. As with any recessive trait, incidences are up to 10-fold higher in areas where consanguinity is common. The conditions discussed in this chapter represent 3% to 5% of all coagulation factor deficiencies. A database (www.rbdd.org) has been established for the purpose of collecting clinical, genetic, and therapeutic information on these disorders to facilitate development of evidenced-based diagnostic and treatment recommendations.

Fig. 139-1, *A,* presents a scheme that reflects our current understanding of the reactions involved in thrombin generation and fibrin formation. Coagulation is triggered by binding of plasma factor VIIa to tissue factor in the wall of a damaged blood vessel. The factor VIIa/tissue factor complex converts factor X to Xa, which in turn converts prothrombin to thrombin in the presence of factor Va. Mice completely lacking prothrombin, factor VII, factor X, or factor V die in utero or soon after birth, demonstrating the importance of these proteins. Thrombin has many functions, including conversion of fibrinogen to fibrin. Factor IX is also activated by factor VIIa/tissue factor and, with factor VIIIa, sustains thrombin generation by activating factor X. In some situations, factor IX activation by factor XIa is required. The older model shown in Fig. 139-1, *B,* serves as the basis for the prothrombin time (PT) and partial thromboplastin time (PTT) assays. Here factor XI activation requires factor XII, prekallikrein and high-molecular-weight kininogen, the contact factors. Deficiency of a contact factor does not result in abnormal bleeding, however, indicating that other mechanisms exist for factor XI activation. For example, thrombin can activate factor XI (see Fig. 139-1, *A*). Finally, factor XIII is activated by thrombin and cross-links fibrin monomers to complete the process of fibrin formation. This chapter contains sections describing deficiency states for each coagulation factor. The number from the Online Mendelian Inheritance in Man (OMIM) database for the deficiency is given in the section title, and each section includes references to websites that compile updated lists of mutations associated with the factor deficiencies. Table 139-1 lists properties of each coagulation factor and features of the congenital deficiency states; Table 139-2 presents recommendations for treatment.

FIBRINOGEN DEFICIENCY (OMIM 202400)

Fibrinogen, the plasma precursor of the fibrin component of a clot, was first purified in the late 19th century. Fibrinogen and fibrin are designated *factor I* and *factor Ia,* respectively, by the International Committee for the Nomenclature of Blood Clotting. Congenital absence of fibrinogen (afibrinogenemia) was first described in 1920 and has an estimated incidence of one in 1 million to 2 million people (see Table 139-1).[1] Partial fibrinogen deficiency is called *hypofibrinogenemia.* Afibrinogenemia and hypofibrinogenemia represent the homozygous and heterozygous states, respectively, for mutations affecting plasma fibrinogen concentration.

Fibrinogen is a 340,000-Dalton protein composed of two heterotrimers, each containing an Aα, Bβ, and γ chain (Fig. 139-2). The three chains are encoded by separate genes (FGA, FGB, FGG) in a 50-kilobase region of chromosome 4. Thrombin converts fibrinogen to fibrin by cleaving fibrinopeptides A and B from the Aα and Bβ chains, respectively. Fibrinogen also binds glycoprotein IIb/IIIa, facilitating platelet aggregation. Fibrinogen is synthesized in hepatocytes. Fibrinogen in platelet α-granules is taken up from plasma via a glycoprotein IIb/IIIa-dependent mechanism. Between 8% and 15% of plasma fibrinogen contains at least one γ chain that is a product of an alternatively spliced mRNA and is referred to as γ′-fibrinogen. The γ′ chain modulates thrombin and factor XIII activity and influences clot architecture.

The normal plasma fibrinogen concentration is 150 to 400 mg/dL (1.5 to 4.0 gm/L). Afibrinogenemic patients have undetectable or very low levels of fibrinogen (<10 mg/dL) as determined by clotting and immunoreactive assays, due to homozygosity or compound heterozygosity for fibrinogen gene mutations. Hypofibrinogenemia is associated with partial deficiency due to heterozygosity for a mutation. Since the first report of a causative mutation in 1999, more than 70 fibrinogen gene abnormalities have been described in afibrinogenemic and hypofibrinogenemic patients (www.geht.org/databaseang/fibrinogen). Most affect the FGA gene and are deletion, frameshift, nonsense, or splicing mutations. Missense mutations are more prevalent in the FGB and FGG genes and cluster in the polypeptide C-termini, affecting formation of the fibrinogen D-domain (see Fig. 139-2) and interfering with secretion. In afibrinogenemia, fibrinogen is not secreted from hepatocytes; this is either a consequence of one of the fibrinogen chains not being synthesized or the result of a mutant chain altering the fibrinogen structure. In either case intracellular nonsecretable fibrinogen polypeptides are usually degraded. A few missense mutations in the FGG gene causing hypofibrinogenemia—for example, Gly284Arg (fibrinogen Brescia), Arg375Trp (fibrinogen Aguadilla), or Thr314Pro (fibrinogen Al DuPont)—are associated with accumulation of mutant γ-polypeptide in hepatocytes, leading to hepatic dysfunction and cirrhosis similar to the process associated with α_1-antitrypsin deficiency (endoplasmic reticulum storage disease).

Acquired hypofibrinogenemia is common in disseminated intravascular coagulation (DIC) and in primary fibrinolysis. Fibrinogen levels are usually normal or increased in liver disease, but levels may

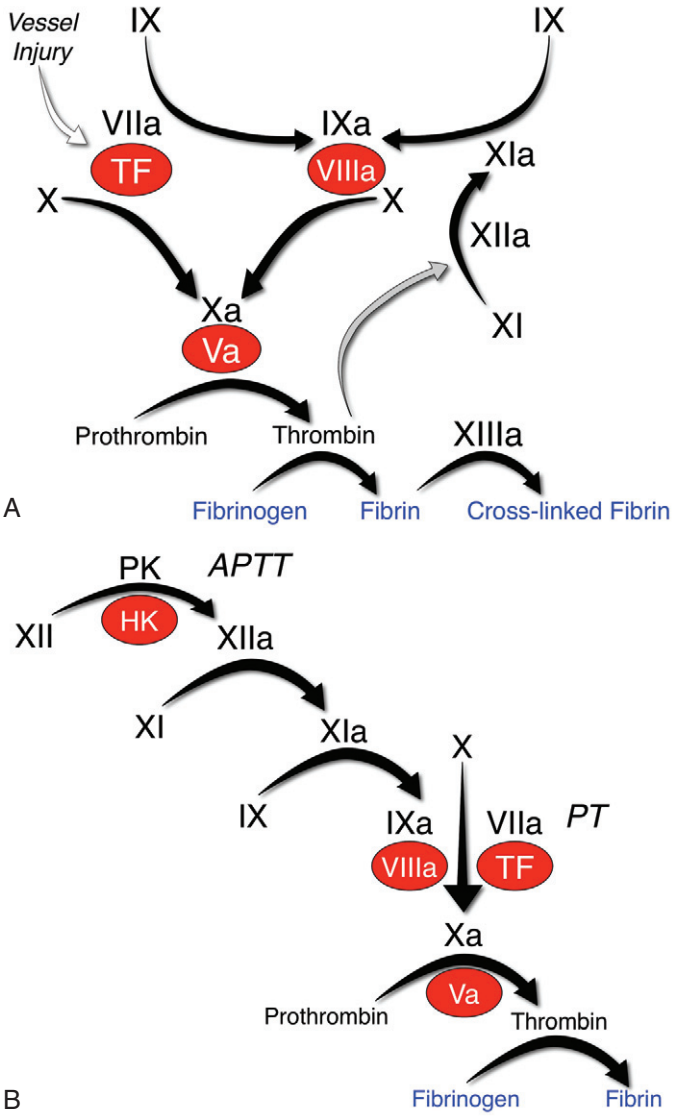

Figure 139-1 MODELS OF PLASMA COAGULATION. Unactivated plasma factors are indicated by Roman numerals and activated factors by Roman numerals followed by a lowercase *a*. Enzymes are indicated by black lettering and cofactors by white lettering in red ovals. Black arrows indicate reactions involving enzyme activation; gray arrow indicates feedback activation of factor XI by thrombin. **A,** A model of tissue factor initiated hemostasis. Please read the introduction to this chapter for a description of the events leading to formation and stabilization of a fibrin clot that are depicted in this figure**. B,** The cascade/waterfall model of hemostasis. This model serves as the basis for the prothrombin time (PT) and activated partial thromboplastin time (PTT) assays. In the PT assay a reagent containing TF is added to plasma, and the factor VIIa/TF complex induces clot formation through activation of factor X. In the PTT assay a reagent containing a negatively charged substance initiates clot formation through activation of factor XII (contact activation; see Fig. 139-3 for details). *TF,* Tissue factor; *HK,* high-molecular-weight kininogen; *PK,* prekallikrein.

be low (<100 mg/dL) in cirrhosis with hepatic failure or with fulminant hepatic necrosis. A low fibrinogen level in patients with hepatic insufficiency indicates a poor prognosis. Patients receiving L-asparaginase for hematologic malignancies may develop severe hypofibrinogenemia (<20 mg/dL), with other coagulation factors being normal or only slightly reduced.

Hemorrhagic symptoms in fibrinogen deficiency are most significant when the plasma level is below 50 mg/dL. Most afibrinogenemic patients (85%) have bleeding from the umbilical cord and from mucosal surfaces.[2] Menorrhagia and bleeding from the skin and the gastrointestinal and genitourinary tracts are common.[3] Hemarthroses and muscle hematomas were frequent in one series (54% and 72%, respectively), but hemarthroses were less frequent (25%) in another study, and hemarthrosis-related arthropathy appears to be less pronounced than in hemophilia. Intracranial bleeding is a major cause of death. Afibrinogenemic patients are also prone to spontaneous rupture of the spleen. Hypofibrinogenemic patients are often asymptomatic, but may have excessive bleeding with trauma or surgery, particularly if the fibrinogen level is <50 mg/dL.

The incidence Pregnancy loss is common in afibrinogenemic and hypofibrinogenemic women, usually in the first trimester.[4] Fibrinogen deficient mice also have difficulty sustaining pregnancies, confirming the importance of the maternal protein to fetal viability. Pre- and postpartum bleeding is common, and intraabdominal bleeding from ruptured corpus luteal cysts has been reported. Of note, arterial and venous thrombotic events have been described in afibrinogenemic patients. Although some cases are associated with other risk factors for thromboembolism (or with administration of replacement therapy), no identifiable risk factor is evident in most instances. Fibrinogen and fibrin have been shown to downregulate thrombin activity, providing a possible explanation for these events.

Assays that measure the time to clot formation, such as the PT, PTT, and thrombin time, will be infinitely prolonged in afibrinogenemia. The template bleeding time and tests of in vitro platelet aggregation are usually abnormal. Fibrinogen is absent, whereas other coagulation factor levels are normal. The von Clauss method is the most commonly used technique for measuring fibrinogen and is based on determining the time to clot formation after addition of thrombin to plasma. This assay is not reliable at low fibrinogen levels (<10 mg/dL) and may give falsely low readings with fibrinogen variants that polymerize slowly (dysfibrinogenemia) or if high levels of substances that interfere with fibrin polymerization (paraproteins, fibrin degradation products) are present. Therefore it is important to demonstrate absence of immunoreactive fibrinogen to confirm a diagnosis of afibrinogenemia. In hypofibrinogenemia functional and antigenic fibrinogen levels are proportionately decreased. A disproportionately low functional level suggests dysfibrinogenemia. The PT and PTT are relatively insensitive to fibrinogen and may not be prolonged with mild to moderate hypofibrinogenemia. The thrombin time is more sensitive in these situations. Afibrinogenemic patients have low erythrocyte sedimentation rates and develop little induration with skin tests for delayed hypersensitivity because of the absence of fibrin deposition.

In 1947, fibrinogen was identified as a major component of cryoprecipitate, which is the preparation used most often in the United States for treating fibrinogen deficiency (Table 139-2). Fresh frozen plasma (FFP) can also be used, although a large volume is required to correct significant fibrinogen deficiency. In 2009, the U.S. Food and Drug Administration (FDA) granted approval for a human fibrinogen concentrate (RiaSTAP) for treating congenital fibrinogen deficiency. In a study of 15 patients given 70 mg/kg of the concentrate, the median plasma fibrinogen concentration 1 hour postinfusion was 130 mg/dL and the half-life of infused fibrinogen was 77.1 hours. Measurement of clot firmness, a surrogate for efficacy, indicated effective treatment in 14 of 15 patients. The results supported those of an earlier study showing that the concentrate was effective in congenital fibrinogen deficiency in 26 of 26 bleeding episodes, 10 of 11 surgeries, and all of 90 prophylactic administrations. The required dose of the fibrinogen concentrate can be determined using the following formula:

$$\text{Dose (mg/kg body weight)} = \frac{(\text{Target level [mg/dL]} - \text{Measured level [mg/dL]})}{1.7\ (\text{kg body weight/dL})}$$

In patients with a normal hematocrit, the plasma volume is ≈40 mL (0.04 liters) per kg body mass. A unit of cryoprecipitate

Table 139-1 Properties of Plasma Coagulation Factors and Characteristics of Deficiency States

Protein	Factor Plasma Half-Life (hr)	Vitamin K Dependent Modification	Factor Level in Pregnancy	Incidence of Severe Congenital Deficiency	Autosomal Inheritance Pattern of Deficiency	Other Names for Deficiency State	Bleeding Diathesis in Severe Deficiency	Screening Tests in Deficiency	
								PT	PTT
Fibrinogen	72-120	No	↑	≈1:1-2 × 10^6	Recessive or dominant	Afibrino-genemia	Severe	↑	↑

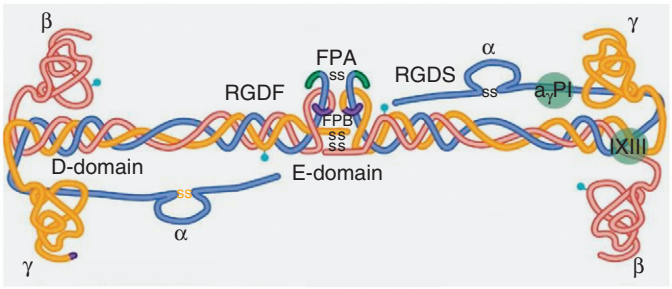

Figure 139-2 MODEL OF HUMAN FIBRINOGEN. A fibrinogen molecule consists of two trimers, each containing an Aα-chain *(blue)*, a Bβ-chain *(pink)*, and a γ-chain *(yellow)*. The amino-termini of the six chains that compose the whole molecule are linked by disulfide bonds in the central E domain, and the C-termini of the polypeptides form two nodular D domains at opposite ends of the molecule. Fibrinopeptides A and B reside in the E domain and are removed by the proteolytic activity of thrombin during conversion of fibrinogen to fibrin monomer. *(Adapted from Mosesson MW: The roles of fibrinogen and fibrin in hemostasis and thrombosis.* Sem Hematol *29:177, 1992, with permission.)*

contains 300 mg of fibrinogen, and administering cryoprecipitate at 1 unit per 5 kg body mass will raise the fibrinogen level of an afibrinogenemic patient to ≈100 mg/dL.

For treatment of significant bleeding, the guidelines of the United Kingdom Haemophilia Centre Doctors Organization recommend that the plasma fibrinogen level be maintained at 100 mg/dL until hemostasis is achieved and above 50 mg/dL until wound healing is complete.[4] A similar strategy makes sense for managing surgical patients. A recent review of replacement therapy and outcomes for 50 patients with congenital fibrinogen deficiency generally agrees with these recommendations.[2] A fibrinogen concentration of 50 to 100 mg/dL was sufficient for prevention or treatment of bleeding in nonsurgical or obstetrical settings, whereas 100 to 200 mg/dL was effective for preventing bleeding during surgery. This review reported that thrombotic episodes (related or unrelated to replacement) occurred in 30% of patients.[2] The half-life of transfused fibrinogen is ≈3 days, and dosing every 2 to 4 days should be adequate to maintain levels in the absence of consumption. Increased dosing frequency may be necessary in cases of massive hemorrhage, major surgery or advanced pregnancy, and close monitoring of the fibrinogen level is recommended to facilitate dosing.

Prophylactic administration of fibrinogen at regular intervals is recommended to maintain pregnancies in afibrinogenemic women and to reduce postpartum hemorrhage.[2] Therapy should be initiated as early as possible, because fetal loss in the first trimester is common. One study suggested that initiating therapy before conception is beneficial.[2] Although some authors recommend keeping fibrinogen levels above 50 mg/dL during pregnancy and peripartum, others suggest a higher level (100 mg/dL) based on reports of fetal loss in patients with levels around 50 mg/dL. Long-term prophylaxis may also be useful in preventing initial bleeding in young patients or to prevent recurrence, particularly after central nervous system hemorrhage. Administration of fibrinogen every 7 to 14 days to maintain plasma levels around 50 mg/dL is recommended.[1]

Antifibrinolytic therapy with ε-amino caproic acid may be an effective replacement for blood products in the case of some mucosal bleeds and for dental extractions (see box on Adjuncts to Factor Replacement Therapy in Congenital Factor Deficiencies). However, this therapy is associated with an increased risk for thrombosis and must be used cautiously in patients with a history of thrombosis, as well as with pregnancy, surgery, or immobilization. Fibrin glue may be useful for tooth extraction, and estrogen/progesterone therapy may be helpful for controlling menorrhagia.

Table 139-2 Treatment Considerations for Rare Coagulation Factor Deficiencies

Protein	Blood Product Sources	Concentrate (Manufacturer)	Minimum Plasma Level Required for Hemostasis	Minimum Plasma Level Required for Surgery	Dose of Preferred Treatment For Surgery or Bleeding	Dosing Frequency for Surgery or Bleeding	Prophylaxis for Severe Deficiency	Pregnancy: Suggested Plasma Levels for Invasive Procedures and Delivery
Fibrinogen	CRYO FFP	RiaSTAP (CSL Behring)*	50 mg/dL	100 mg/dL	70 mg/kg†	Q 24-72 hr depending on consumption	Keep level 50 mg/dL for recurrent bleeders	Maintain at 100 mg/dL throughout pregnancy
Prothrombin	FFP	PCC*	≈5%	30%	20-30 factor IX units/kg	Q 48-72 hr	40 factor IX units/kg Q 5-6 days	20%-30%
Factor V	FFP* platelets	None	≈10%	25%	15-20 mL FFP/kg then 5-10 mL/kg q12 hr	Q 12-24 hr	Not usually required	15%-25%
Factor VII	FFP	NovoSeven* (recombinant factor VIIa, Novo Nordisk) PCC	5%-10%	15%-25%	15-30 mcg factor VIIa/kg	Q 2-6 hr	20-30 mcg/kg 2-3 times per wk	10%-20%
Factor X	FFP	PCC* Factor X concentrate (BioProducts Laboratory—Investigational)	≈10%	25%-40%	15-20 factor IX units/kg	Q 24 hr	15-20 factor X units/kg Q weekly	10%-20%
Factor XI	FFP	Hemoleven* (LFB Biomedicaments); Factor XI concentrate (BioProducts Laboratory)	15%	30%-40%	15-20 factor XI units/kg	Q 1-2 days	Not required	May withhold treatment unless bleeding. 20%-40% if bleeding occurs
Factor XIII	CRYO FFP	Corifact* (Formerly Fibrogammin P, CSL Behring) Recombinant Factor XIII (Novo Nordisk—Investigational)	1%-2%	20%-50%	20-30 factor XIII units/kg	Single dose may be sufficient	40 factor XIII units/kg Q 28 days	250 units/wk through wk 22, then 500 units/wk with a 1000 unit bolus during labor

Adjuncts to Factor Replacement Therapy in Congenital Factor Deficiencies

The antifibrinolytic agents ε-amino caproic acid and tranexamic acid can be effective adjuncts to factor replacement when treating congenital or acquired bleeding disorders and may be useful alternatives to replacement therapy for mild bleeding or minor procedures. These drugs inhibit clot dissolution by blocking plasminogen activation and plasmin activity and are particularly valuable when bleeding involves tissues with high fibrinolytic activity such as the oral cavity. They are also useful for treating menorrhagia, limiting blood loss with surgery, controlling epistaxis, and reducing some types of gastrointestinal bleeding. A typical loading dose of ε-amino caproic acid is 50 to 100 mg/kg followed by 2 to 4 grams every 6 hours. If bleeding subsequently occurs, the dose can be increased to a maximum of 24 grams in 24 hours. ε-Amino caproic acid is available in oral and intravenous formulations. Identical dosing may be used for either preparation because of excellent bioavailability. For dental extraction in factor VIII or IX deficiency, many centers use a single 50% to 100% loading dose of clotting factor concentrate followed by seven days of ε-amino caproic acid as the sole prophylaxis, and it is reasonable to extrapolate this approach to patients with some of the rare bleeding disorders. Patients with factor XI deficiency do well with antifibrinolytic agents alone for tooth extractions. Dental procedures such as scaling or root canal can be performed safely using ε-amino caproic acid or tranexamic acid mouthwash prepared from the intravenous formulation three to four times daily with or without systemic antifibrinolytic therapy.

Prolonged therapy with antifibrinolytic agents must be undertaken with caution in patients who are not mobile, who have a history of thromboembolic events, or who have significant urogenital bleeding. These drugs interfere with urokinase-mediated fibrinolytic activity in the genitourinary tract and can cause renal outflow obstruction by thrombotic occlusion of the ureters. Concomitant use of antifibrinolytic agents with activated prothrombin complex concentrates or recombinant factor VIIa may result in a particularly high risk for thrombus formation. Patients may develop nausea or vertigo with high doses of ε-amino caproic doses, and rarely, rhabdomyolysis.

Hemorrhage may be controlled or prevented in rare bleeding disorders with recombinant factor VIIa. The mechanism by which this agent works is not completely understood in all situations, particularly for deficiencies of factors in the common pathway (prothrombin and factors V and X). For patients with rare bleeding disorders and an immunoglobulin inhibitor directed against the missing factor, factor VIIa may be the treatment of choice. Doses range from 15 to 120 mcg/kg every 2 to 6 hours depending upon the severity of bleeding. In factor XI–deficient patients without inhibitors, doses of 15 to 30 mcg/kg every 2 to 4 hours are often sufficient. A dose of 90 mcg/kg every 2 to 3 hours has been used in patients with congenital factor V deficiency or combined deficiencies of factors V and VIII, patients with acquired factor X deficiency associated with amyloidosis, and patients with antibody-mediated acquired prothrombin deficiency associated with lupus anticoagulants. An attractive aspect of using factor VIIa in place of FFP is the smaller volume of material infused. Factor VIIa is also associated with a lower risk for reactions associated with plasma infusions such as fever, urticaria, transfusion-related acute lung injury (TRALI), and anaphylaxis. Caution must be exercised when using factor VIIa in older patients with cardiovascular disease, because arterial thrombosis can result, particularly when therapy is combined with fibrinolytic inhibitors or prothrombin complex concentrate.

DYSFIBRINOGENEMIA (OMIM 134820 Aα-CHAIN, 134830 Bβ-CHAIN, AND 134850 γ-CHAIN)

In dysfibrinogenemia, structural variants of fibrinogen circulate in plasma. Cases in which the dysfunctional protein is present at low levels may be referred to as *hypodysfibrinogenemia*. The first family with dysfibrinogenemia (15 amino acid insertion after Gln350 in the γ-chain [fibrinogen Paris I]) was described in 1964. The actual incidence of congenital dysfibrinognemia is not known, because the majority of patients are probably asymptomatic and do not come to medical attention.

Congenital dysfibrinogenemias are almost all autosomal dominant conditions caused by a missense mutation in one of the fibrinogen genes, although some insertions and deletions have been identified (www.geht.or/databaseand/fibrinogen). Amino acid substitutions that alter fibrinopeptide release, fibrin cross-linking, fibrin polymerization, or fibrin degradation have been reported. The diagnosis of dysfibrinogenemia is established by identification of a low fibrinogen activity in a rate-based clotting assay relative to immunoreactive fibrinogen. The types of functional defects most often reported, therefore, are undoubtedly influenced by the assays available in clinical laboratories and are unlikely to represent the full spectrum of mutations that can cause fibrinogen dysfunction. Variants readily detected by the assays used in clinical laboratories typically have defects in fibrinopeptide release (e.g., FGA-Arg16His and FGA-Arg16Cys [fibrinogens Bicêtre and Metz]), or polymerize slowly (e.g., FGG-Ser434Asn [fibrinogen Caracas II], FGG-Arg275Cys and FGG-Arg275His). Indeed, ≈45% of the mutations associated with dysfibrinogenemia in the database involve substitutions at FGA-Arg16 or FGG-Arg275, at least partly reflecting the ease with which these variants can be detected with commonly used functional assays.

Most patients with dysfibrinogenemia (55% to 60%) are asymptomatic, and the condition is identified by an abnormal result on a coagulation screening assay. Excessive bleeding occurs in ≈25%, whereas 20% have thrombotic episodes. The correlation between functional abnormalities and symptoms is often weak. For example, the common FGA-Arg16His and FGA-Arg16Cys variants have been reported in asymptomatic individuals as well as patients with bleeding or thrombosis. Epistaxis, easy bruising, and menorrhagia are relatively common in those with symptoms. Although bleeding is often mild, soft tissue hematomas, hemarthroses, postoperative hemorrhage, and bleeding during pregnancy and peripartum may occur. Abnormal wound healing and spontaneous abortions have been reported. Thrombotic events primarily involve the venous circulation, although some arterial events have been reported. About one quarter of patients with thrombotic symptoms also experience excessive bleeding.

In 1995, a subcommittee of the International Society on Thrombosis and Haemostasis determined that a significant relationship exists between certain fibrinogen variants and venous thrombosis. However, in a review of 2376 patients with venous thrombosis, dysfibrinogenemia was found in less than 1%, so testing for dysfibrinogenemia is not widely recommended in this setting. Mutations associated with thrombosis tend to cluster at the C-terminus of the Aα-chain and near the thrombin cleavage site on the Bβ chain. Abnormalities in fibrin polymerization, cross-linking, clot structure, and susceptibility to fibrinolysis have been described. The "Dusart syndrome" caused by FGA-Arg554Cys (fibrinogen Paris V) has been associated with venous thrombosis and sudden death in teenagers and young adults in several families. Recently, dysfibrinogenemia was reported in 5 of 33 patients with chronic thromboembolic pulmonary hypertension.[5] The FGB-Pro235Leu mutation was found in three unrelated patients in this study. Dysfibrinogenemias were associated with altered fibrin polymer structure and/or susceptibility to lysis, suggesting that the involved fibrinogen variants predispose to incomplete clot dissolution.

A group of mutations in the C-terminus of the fibrinogen Aα-chain is associated with autosomal dominant hereditary amyloidosis. The amyloid deposits contain fragments of the variant fibrinogen.

The kidneys are initially affected, but wider visceral and nerve involvement may occur. Renal grafts subsequently become involved with amyloid, and liver transplantation may be a better treatment option. The allele for one responsible mutation, FGA-Glu526Val, is relatively common and may account for 5% of patients with apparent sporadic amyloid.

Acquired dysfibrinogenemia is most frequently diagnosed in severe liver disease, with 80% to 90% of patients with cirrhosis or liver failure showing some degree of fibrinogen dysfunction. Increased sialic acid content is likely responsible for impaired fibrin polymerization. Despite abnormalities in coagulation assays, the process probably does not contribute substantially to abnormal hemostasis. Homocysteine-induced modifications of fibrinogen have been proposed to contribute to the hypercoagulable state associated with elevated plasma levels of homocysteine. The monoclonal antibody in patients with multiple myeloma can interfere nonspecifically with fibrin polymerization but usually does not cause abnormal hemostasis. Acquired dysfibrinogenemia has been associated with other malignancies and bone marrow transplantation.

Most cases of dysfibrinogenemia present as abnormalities on routine coagulation tests such as the PT and PTT. The thrombin time is often used as a primary screening test for dysfibrinogenemia, although its sensitivity is not established. The test involves measuring the time to clot formation in citrated plasma after addition of a standard amount of thrombin. The specificity of the test is relatively poor; heparin, elevated fibrin degradation products, paraproteins, and low levels of fibrinogen all may affect results. The reptilase time has been used as an alternative screen for dysfibrinogenemia and is useful in combination with the thrombin time. The assay involves inducing clot formation with an enzyme from the venom of *Bothrops jararaca* or *Bothrops atrox* that cleaves fibrinopeptide A (but not fibrinopeptide B) from fibrinogen and is not sensitive to heparin. The apparent plasma concentration of clottable fibrinogen as determined by the von Clauss method (see section on Fibrinogen Deficiency) may be low in some types of dysfibrinogenemia. Levels of immunoreactive fibrinogen are usually normal, but they are decreased in cases of hypodysfibrinogenemia. With some variants, serum fibrin degradation products may appear to be elevated using certain assays because the variant fibrinogen is incompletely incorporated into the clot. This can lead to the false impression that DIC is present.

Most dysfibrinogenemic patients are asymptomatic, and symptoms correlate poorly with coagulation assay abnormalities, making it difficult to generalize regarding therapeutic recommendations. The patient's personal and family histories are useful for guiding therapy. Active bleeding can be treated with replacement therapy, as in afibrinogenemia, and such treatment may be indicated in some patients before invasive procedures. In general, patients with thrombosis and dysfibrinogenemia should be treated similarly to other patients with hypercoagulable conditions. There are no data on which to formulate recommendations as to duration of therapy; thus past history, family history, coexisting conditions, and the nature (idiopathic, pregnancy-related or postsurgery-related) and seriousness of the thrombosis must all be taken into consideration. As with any thrombotic event, the risk for bleeding associated with prolonged therapy must be considered. Recurrent spontaneous abortions have been associated with dysfibrinogenemia in several families, and some pregnancies have been carried to term using replacement therapy with cryoprecipitate.

PROTHROMBIN DEFICIENCY (OMIM 176930)

More than a century ago, Morawitz proposed that an insoluble fibrin clot is formed from fibrinogen through the activity of fibrin ferment or thrombin. Thrombin was generated from a precursor, prothrombin, by thrombokinase (probably factor Xa). Prothrombin and thrombin are designated *factors II* and *IIa.* Total prothrombin deficiency is probably not compatible with life, because complete absence of the protein has not been observed in humans and prothrombin-deficient mice succumb to bleeding in utero or shortly after birth. Severe congenital deficiency associated with reduced plasma prothrombin antigen (hypoprothrombinemia) or circulating dysfunctional prothrombin (dysprothrombinemia) affects an estimated 1 in 2 million people (see Table 139-1). Prothrombin deficiency is the third most common coagulation factor disorder in Puerto Rico (carrier frequency ≈1 in 700), accounting for 6% of non–von Willebrand disease congenital bleeding disorders at the University of Puerto Rico Hemophilia Center. In the North American Rare Bleeding Disorder Registry, 62% of patients with prothrombin deficiency were Latino, possibly reflecting the prevalence of the Arg457Gln variant prothrombin Puerto Rico I.

Prothrombin is a 72,000-Dalton protein that is converted to thrombin by factor Xa in complex with factor Va on phospholipid surfaces (see Fig. 139-1, *A*). Thrombin is a pivotal protease in hemostasis, with multiple procoagulant activities including cleavage of fibrinopeptides A and B from fibrinogen to form fibrin (see Fig. 139-2), activation of factors V, VIII, XI, and XIII, and cleavage of protease activated receptors on a variety of cells including platelets.[6] Thrombin forms a complex with thrombomodulin on endothelial cells to downregulate fibrinolysis by activating thrombin-activatable fibrinolysis inhibitor (TAFI) and to downregulate coagulation by activating protein C. Thrombin also has cytokine and growth factor–like properties.

Prothrombin deficiency is an autosomal recessive disorder manifested as hypoprothrombinemia (reduced activity and antigen; cross-reactive material–negative [CRM−] deficiency), dysprothrombinemia (activity reduced relative to antigen; cross-reactive material–positive [CRM+] deficiency) or a combination of both. Plasma prothrombin activity is typically 1% to 10% of normal in hypoprothrombinemia and 1% to 20% in dysprothrombinemia. Heterozygotes for either condition have 40% to 60% normal activity. More than 50 prothrombin gene mutations have been described (www.isth.org/default/index.cfm; www.hgmd.org) in patients with prothrombin deficiency, with ≈80% being missense mutations.[6] In dysprothrombinemia, missense mutations typically cause defects in prothrombin conversion to thrombin (e.g., prothrombin Arg457Gln [Puerto Rico I] and Arg-271Cys [Madrid]), or result in functionally defective thrombin (e.g., prothrombin Arg418Trp [Tokushima]).

Prothrombin deficiency can be inherited in combination with deficiencies of other vitamin K–dependent proteins (see Combined Deficiency of Vitamin K–Dependent Proteins). Acquired prothrombin deficiency occurs with warfarin therapy, as well as in cases of poisoning with rodenticides such as brodifacoum, vitamin K deficiency, liver disease, and DIC. Cephalosporins, particularly those with N-methyl-thiotetrazole side chains, can decrease prothrombin levels. Antiprothrombin antibodies are common phospholipid-dependent antibodies found in patients with the lupus anticoagulant or the antiphospholipid antibody syndrome. More rarely, patients with a lupus anticoagulant or systemic lupus erythematosus have antibodies that enhance prothrombin clearance, causing true deficiency. No reports exist of neutralizing antibodies forming after replacement therapy in congenital prothrombin deficiency, consistent with severely affected patients having at least a trace of circulating prothrombin.

Severe hypoprothrombinemia is inevitably associated with bleeding that may be life threatening, although the correlation between plasma prothrombin activity and clinical severity is not particularly strong. Central nervous system hemorrhage was reported in 8% to 12% of patients, and in 20% of those with prothrombin levels below 1% of normal activity.[6] Soft tissue hematomas, bruising (60%), and hemarthroses (42%) are common. The bleeding diathesis can present at circumcision in neonates or as easy bruising, epistaxis, menorrhagia, or gastrointestinal hemorrhage, as well as with trauma or surgery. Heterozygotes occasionally have excessive bleeding with surgery or tooth extraction, but most are asymptomatic. Bleeding tends to be less severe in dysprothrombinemia, and some variants are particularly mild. For example, homozygosity for Arg67His causes severe reduction in plasma prothrombin activity (<20% of normal) but results in relatively few symptoms.

In the PT and PTT assays, prothrombin is converted to thrombin by factor Xa in complex with factor Va on phospholipids surfaces (see

Fig. 139-1, *B*), and severe prothrombin deficiency will prolong both test results. Some PT and PTT reagents are relatively insensitive to reductions in prothrombin, and mild deficiencies may be missed. The diagnosis is confirmed, and the degree of deficiency established, by a modified PT assay using prothrombin-deficient plasma. Prothrombin deficiency must be distinguished from deficiencies of fibrinogen, factor V, or factor X, which are also associated with a prolonged PT and PTT.

Prothrombin complex concentrate (PCC), approved for use in factor IX deficiency, contains varying amounts of prothrombin and factors VII and X (see Table 139-2) and is the preferred product for treating prothrombin deficiency. PCC is derived from human plasma and undergoes viral inactivation. The prothrombin activity in a typical PCC is usually comparable to, or higher than, factor IX activity. Hemostatic levels of prothrombin are estimated to be 20% to 40% of normal for major surgery or trauma, but 10% to 15% may be adequate for milder hemostatic challenges. A dose of 20 to 30 factor IX units/kg of PCC usually produces plasma prothrombin levels of 20% to 30% of normal. The half-life of prothrombin is about 3 days, and dosing every 2 to 3 days can maintain adequate levels until healing is complete. Alternatively, one-fourth of the loading dose each day should keep the level therapeutic. Prophylactic infusion of PCC every 5 to 6 days prevented spontaneous bleeding in one severely deficient patient. PCC administration has been associated with thrombosis, although a recent meta-analysis of studies using PCC preparations to reverse the anticoagulant effect of warfarin suggests the risk is relatively low (<2%).[7] It seems reasonable to maintain the factor VII, IX, and X levels at <150% of normal to reduce risk. Dental procedures or minor hemorrhage may respond to antifibrinolytic therapy with ε-amino caproic acid. Prothrombin deficiency may also be treated with FFP for bleeding episodes or surgical intervention (15 to 20 mL/kg loading dose followed by 3 mL/kg/day). Because of the long half-life, additional doses may not be required in all situations. Cryoprecipitate is not a source of prothrombin, and plasma prothrombin levels do not increase after infusion or inhalation of desmopressin (1-desamino-8-D-arginine vasopressin [DDAVP]).

Treatment of acquired prothrombin deficiency associated with lupus anticoagulants requires immunosuppression, most commonly with steroids. This is effective in most patients, although many relapse during weaning or after stopping treatment. Subsequent treatment with azathioprine or cyclophosphamide has successfully eradicated the antibody. Rituximab has also been reported to be effective, and we have observed this in our own practice. In a rare case of quinidine-induced lupus anticoagulant with concomitant antiprothrombin antibody, cessation of the drug led to spontaneous resolution of acquired prothrombin deficiency, but not the lupus anticoagulant. The low prothrombin activity in these patients may protect them from thrombosis, as reports of thrombosis after successful eradication of the antiprothrombin antibody suggest.

FACTOR V DEFICIENCY (OMIM 227400)

In 1943, Quick reported that aged plasma clotted more slowly than fresh plasma in a prothrombin time assay and proposed that a labile factor distinct from prothrombin was required for normal coagulation. At the same time, Owren noted that a patient with a lifelong bleeding problem lacked a factor normally found in plasma that, in contrast to prothrombin, did not adsorb onto aluminum hydroxide. Owren's patient was deficient in the labile factor described by Quick, which is now called factor V. Severe congenital factor V deficiency has been estimated to occur in 1 in 1 million persons (see Table 139-1).

Factor V is the 330,000-Dalton precursor of the cofactor factor Va, which facilitates prothrombin activation by factor Xa on phospholipid surfaces (Fig. 139-1, *A*). Severe factor V deficiency is an autosomal recessive trait with plasma factor V activity of 1% to 10% of normal.[8-10] More than 100 factor V gene mutations associated with factor V deficiency have been described (www.isth.org/default/index.cfm; www.hgmd.org). Nonsense and frameshift mutations are distributed throughout the gene, whereas missense mutations cluster in the A2 and C2 domains. Missense mutations usually result in abnormal polypeptides that are degraded within the cell, resulting in low plasma factor V antigen (CRM deficiency). The only well characterized CRM+ mutation is factor V New Brunswick [Ala221Val], which interferes with factor Va stability. Most (80%) of the factor V in blood is in plasma, with the remainder stored in a partially activated form in platelet α-granules. In humans, platelet factor V is primarily of plasma origin. After being taken up from the plasma, factor V is modified by platelets so that it is more procoagulant than plasma factor V. Some patients with very low plasma factor V levels and mild bleeding symptoms have sufficient platelet factor V to maintain thrombin generation. This implies that factor V is unstable in plasma but can still be taken up and stored by platelets. Patients with more severe bleeding symptoms may lack both plasma and platelet factor V activity.

Factor V deficiency can be inherited by mechanisms unrelated to mutations in the factor V gene. Combined factor V and factor VIII deficiency is caused by mutations in proteins required for secretion of both factors (discussed in Combined Factor V and Factor VIII Deficiency).[9,10] A few patients have been identified with abnormalities specific to platelet factor V. The Quebec platelet disorder is an autosomal dominant bleeding condition with low platelet factor V levels and normal plasma factor V. Proteolytic degradation of multiple α-granule proteins in this syndrome is due to overexpression of urokinase-type plasminogen activator. Platelet factor V activity is also reduced in Factor V New York, but the underlying mechanism is not known.

Acquired antibodies to factor V may present in a variety of ways ranging from asymptomatic laboratory abnormalities to life-threatening hemorrhage. Alloantibodies to factor V were often associated with exposure to topical bovine thrombin during surgery. These preparations contained bovine factor V, and the resulting antibodies cross-reacted with human factor V. This problem rarely occurs now because recombinant thrombin preparations are used instead of the bovine material. Alloantibodies to factor V also occur in some factor V–deficient patients exposed to human plasma. Factor V autoantibodies may develop after surgery or blood transfusions or with cancer, autoimmune disorders, or therapy with β-lactam or aminoglycoside antibiotics. Acquired factor V deficiency may occur with liver disease, DIC, and systemic amyloidosis.

There is considerable variation in bleeding among patients with severe factor V deficiency (1% to 10% of normal levels).[8-10] Although significant bleeding does occur, the frequency tends to be less than in cases of severe factor VIII or factor IX deficiency. Variability may be related partly to the amount of factor V associated with platelets. Mucosal bleeding is the primary abnormality, with 60% of patients experiencing epistaxis, menorrhagia, or oral bleeding. Hematomas and hemarthroses occur in 25% of patients, but debilitating arthropathy is uncommon. Severe bleeding in the central nervous system or gastrointestinal tract has been reported, but this is relatively rare. Postpartum hemorrhage is common. Trauma, surgery, and dental extraction are associated with a high risk for bleeding in untreated patients. Bleeding with surgery involving the urogenital tract, the nose, or the mouth may be particularly problematic because of high local fibrinolytic activity. Mild (heterozygous) factor V deficiency (25% to 60% of normal factor level) is usually not associated with excessive bleeding, although ≈10% of patients report some bleeding.

Thrombosis has been reported in factor V–deficient patients. In some cases, the deficiency may simply have not been sufficient to prevent thrombosis. Indeed, with the exception of deficiency of prothrombin or factor X, thrombotic events have been reported in all severe coagulation factor deficiency states. However, the situation with factor V is more complex. Deficiency can occur in patients with the common procoagulant factor V polymorphism Arg506Gln (factor V Leiden). If Arg506Gln and a mutation causing deficiency occur on opposite alleles (in-trans), most of the factor V in the blood will have the Gln506 substitution, which will significantly increase the risk for thrombosis (pseudohomozygous activated protein C

resistance). Alternatively, Arg506Gln may occur on the same allele as a null mutation (in-cis), which will mask the prothrombotic effect of Arg506Gln. Such patients may have a bleeding tendency.

Factor V is required for normal prothrombin activation by factor Xa in the prothrombinase complex (see Fig. 139-1, *B*), and factor V deficiency causes prolongation of both the PT and PTT. The diagnosis and severity are established using a modified PT assay with factor V–deficient plasma. In some cases of severe deficiency, the template bleeding time is prolonged. Patients with factor V deficiency should be tested for factor VIII deficiency so that combined deficiency is not missed. Factor V inhibitors cause prolongations of the PT and PTT that do not correct on mixing with normal plasma. Like the situation with factor VIII inhibitors, factor V inhibitor titers are established using the Bethesda method. However, unlike the more common inhibitors to factor VIII, which typically take 1 to 2 hours of incubation to fully inactivate their target, factor V inhibitors inhibit factor V almost immediately. The thrombin time should be normal, except in cases of inhibition induced by bovine topical thrombin, where antithrombin antibodies against thrombin are also present.

No factor V concentrate is commercially available with which to treat deficient patients (see Table 139-2). Administration of FFP is recommended for serious bleeding or in preparation for surgery. The minimum factor V level for hemostasis is estimated to be ≈15%.[8] In a patient with less than 1% plasma factor V, this can be achieved by administering 15 to 20 mL/kg FFP, followed by 5 mL/kg every 12 hours. A plasma level of at least 25% is recommended for major surgery. Estimates of the factor V plasma half-life vary widely, but 12 to 14 hours can be assumed for replacement purposes. Infusion of 20 mL/kg FFP (over 3 to 4 hours) before surgery, followed by 5 to 10 mL/kg every 12 hours thereafter is usually adequate. Infusions should be continued for 7 to 10 days to establish wound healing. Care must be taken to avoid fluid overload from large volumes of FFP, particularly in older patients. Plasma exchange has been successful in a few factor V–deficient patients requiring surgery. Mucosal bleeding from the nose and mouth may respond to ε-amino caproic acid, and superficial lacerations often respond to local pressure. Although the defect caused by factor V deficiency would hypothetically render therapy with recombinant factor VIIa ineffective, this agent has been used successfully in a patient with severe factor V deficiency requiring surgery.

Menorrhagia is common in a factor V–deficient women. Symptoms may be managed by antifibrinolytic therapy (ε-amino caproic acid 50 to 60 mg/kg every 4 to 6 hours or tranexamic acid 15 mg/kg every 6 to 8 hours), oral contraceptives, levonorgesterol intrauterine devices, replacement therapy, or surgical intervention (endometrial ablation or hysterectomy). Replacement should be adjusted to maintain a factor V level of ≈15% of normal. Factor V–deficient women may have significant bleeding with childbirth and should be treated in a similar manner.

Platelets are a source of factor V and may be particularly useful in patients with severe bleeding or factor V inhibitors. Platelet factor V may either be protected from inhibition or may be sufficiently different in structure from its plasma counterpart to not cross-react with antibodies directed at factor V. However, platelet transfusions are not recommended as routine first-line treatment for factor V deficiency because of the possibility of developing antiplatelet alloantibodies. Cryoprecipitate is not a source of factor V, and plasma levels do not respond to administration of DDAVP.

FACTOR VII DEFICIENCY (OMIM 227500)

Factor VII deficiency was first reported by Alexander and colleagues in 1951. Severe factor VII deficiency is the most common of the nonhemophilic coagulation factor deficiencies (see Table 139-1), with an estimated prevalence of 1 in 500,000 persons.[11-13]

Factor VII is the 50,000-Dalton precursor of the protease factor VIIa. Factor VII/VIIa binds to tissue factor to initiate coagulation through activation of factors X and IX (see Fig. 139-1, *A*). A cut-off value for severe factor VII deficiency has not been firmly established, but a value of less than 2% of normal has been proposed. A severity classification system based on clinical presentation has also been suggested.[11] Mice lacking factor VII develop normally in utero but succumb to bleeding at birth. An infant born with complete absence of factor VII died from intracranial hemorrhage 12 days after birth, whereas another survived with replacement therapy. Thus low levels of factor VII activity appear to be necessary to sustain life. Although factor VII deficiency is usually considered an autosomal recessive trait, the fact that bleeding symptoms occur in up to 36% of patients with heterozygous deficiency raises questions about this concept.[13]

More than 250 factor VII gene mutations associated with factor VII deficiency have been described (www.isth.org/default/index.cfm), two-thirds of which are missense mutations. Although most have been identified in single families, some are more widespread. In surveys of patients from Europe and Latin America, Ala244Val accounted for 84% of abnormal factor VII alleles in 88 unrelated Jewish patients and in 14% and 7% of abnormal factor VII alleles in Germany and France, respectively.[13] CRM+ variants are common. Some factor VII variants demonstrate variable activity in the PT assay, depending on the species of origin of the tissue factor in the thromboplastin reagent employed. The name "factor VII Padua" has been applied to these variants, and a number of cases are associated with a missense mutation (Arg304Gln) that causes a major defect in the interaction with rabbit tissue factor but not with human or ox tissue factor.

Factor VII deficiency may occur in combination with deficiencies of other vitamin K–dependent proteins (discussed in Combined Deficiency of Vitamin K–Dependent Proteins) and in combination with factor X deficiency as a result of loss of both genes due to a chromosome 13 q34 deletion. Factor VII deficiency has also been reported in cases of trisomy 8 and in conjunction with abnormalities of bilirubin metabolism, mental retardation, microcephaly, epicanthus, cleft palate, and patent ductus arteriosus.

Reduced levels of factor VII occur with warfarin therapy, liver disease, DIC, biliary tract disease, vitamin K deficiency, and cephalosporin therapy. In these situations other vitamin K–dependent factors are usually decreased, although the effect on factor VII is often the greatest because of its shorter half-life. Alloantibody inhibitors to factor VII have been reported in deficient patients after replacement therapy.[14] Acquired factor VII deficiency has been reported as a paraneoplastic syndrome with atrial myxoma and Wilms tumor. Other scenarios rarely associated with low factor VII include hematopoietic stem cell transplantation, aplastic anemia, and sepsis.

The clinical spectrum of bleeding in factor VII deficiency is broad. Not surprisingly, significant bleeding tends to be greatest with severe deficiency, and patients with levels less than 1% of normal may have a syndrome similar to severe hemophilia, with spontaneous joint and soft tissue bleeding and hemarthrosis-related arthropathy.[11-13] Of interest, a comparison of bleeding in factor VII and factor IX deficiency indicated that lower levels of factor VII sustain hemostasis better than comparable levels of factor IX. Central nervous system hemorrhage is relatively common (4% to 17%).[12,15] Patients with factor VII activity of ≥5% of normal tend to have milder symptoms such as epistaxis, menorrhagia, and bruising. Although little bleeding occurs in most patients with factor VII levels 10% to 15% of normal, some describe significant bleeding, either spontaneously or in response to hemostatic challenges. In one study, 36% of heterozygotes (factor VII activity 21% to 69%) reported bleeding problems, mostly involving skin and mucous membranes, whereas another study reported a greater risk for subcutaneous bleeding in heterozygotes. Excessive bleeding often complicates dental extraction and surgery on the oropharynx or urogenital tract in untreated patients. Abdominal surgery and hysterectomy are associated with fewer problems, likely reflecting varying levels of fibrinolytic activity in different tissues. Postpartum bleeding is not common in factor VII–deficient women because factor VII levels rise in late pregnancy in all but the most severely deficient patients. The need for prophylaxis to prevent bleeding correlates best with baseline factor VII levels less than 10% to 15% of normal.

Thrombosis associated with factor VII deficiency has been well documented. A study of 33 reported cases (6 arterial, 27 venous) revealed 15 with molecular studies. Nearly all patients had other thrombotic risk factors, usually acquired, and four had congenital thrombophilia. Of the 15 patients, 11 had either Arg304Gln (Factor VII Padua) or Ala294Val. Those with factor VII Padua had no bleeding history, whereas mild bleeding was reported with Ala294Val. Treatment of thrombosis with vitamin K antagonists is problematic in these cases because the baseline PT is abnormal as a result of the mutation. Therapy with low-molecular-weight heparin or one of the newer direct thrombin or factor Xa inhibitors may be a better option.

In the PT, factor VII/VIIa binds tissue factor supplied by the thromboplastin reagent. The factor VIIa/tissue factor complex then activates factor X (see Fig. 139-1, *B*). In factor VII deficiency, the PT is prolonged and the PTT is normal. The diagnosis is confirmed, and the severity determined, by a modified PT assay using factor VII–deficient plasma. With very sensitive thromboplastin reagents, the PT may be prolonged with factor VII levels at the lower end of the normal range. When assessing patients for factor VII deficiency, the source of the tissue factor must be considered, because some factor VII variants bind poorly to tissue factor from certain species. Factor VII Padua–type variants interact poorly with the rabbit tissue factor–based reagents widely used in North America; they function better with human tissue factor and best with ox tissue factor. We routinely retest patients with apparent factor VII deficiency in rabbit tissue factor-based assays with a human tissue factor thromboplastin reagent to detect Padua-type variants.

Major considerations when treating factor VII–deficient patients include the short plasma half-life of the protein (3 to 4 hours), relatively low recovery of infused material (possibly due to a large volume of distribution), and rapid clearance in children. A plasma factor VII level of 10% to 15% of normal is probably the minimum required for surgery, with 15% to 25% being adequate in most cases. Of 157 surgeries performed on 83 factor VII–deficient patients with a mean baseline activity of 5% who did not receive prophylaxis, 15.3% had bleeding complications.[16] The data suggest that supplementing patients with baseline levels below 10% should reliably exclude hemorrhage. Factor replacement can be accomplished with several products (see Table 139-2). FFP is widely used, but its effectiveness is limited because of the large volumes that must be administered. PCC contains variable amounts of factor VII. However, these products are not favored, because they contain other vitamin K–dependent factors in higher concentrations than factor VII, which could increase the risk for thrombosis. Recombinant factor VIIa is considered the optimal therapy for treating or preventing bleeding in factor VII deficiency. A dose of 15 to 30 mcg/kg body weight every 2 to 6 hours will usually achieve hemostasis, with the frequency adjusted to the clinical situation.[11,12] Hemarthroses often respond to single infusions. Prophylaxis for invasive procedures may require treatment every 2 to 3 hours. In a study of 41 surgeries in 34 factor VII–deficient subjects receiving factor VIIa, bleeding occurred in only three instances, and in those, the factor VIIa dose was considered low. Adequate replacement to prevent bleeding was determined to be at least 13 mcg/kg body weight per dose and no less than three doses administered on the day of surgery. Administration of factor VIIa by continuous infusion has been used successfully to cover surgical procedure and may reduce the total amount of drug administered by 70% to 90% compared with bolus infusions.

Patients with severe factor VII deficiency may benefit from secondary prophylaxis to prevent further life-threatening bleeding, particularly bleeding in the central nervous system, which is associated with a mortality rate of 50% to 70%. Although, several replacement products have been used in this situation, recombinant factor VIIa is the preferred agent. Despite its short half-life, factor VIIa can be effective at doses of 20 to 30 mcg/kg given 2 to 3 times per week.[17] Three cases of inhibitor formation have been reported. Not all bleeding episodes in factor VII–deficient patients require replacement therapy. Minor injuries may be controlled with local measures. Fibrinolytic inhibitors, such as ε-amino caproic acid, may be effective for minor bleeding, dental surgery, or other procedures involving mucous membranes. Fibrin glue may also be effective in some situations. Cryoprecipitate is not a source of factor VII, and plasma levels do not respond to administration of DDAVP.

FACTOR X DEFICIENCY (OMIM 227600)

Factor X deficiency was first described in two patients more than 50 years ago. The missing plasma factor was initially called *Stuart-Prower factor* after the two index cases and was subsequently designated *factor X*. Patient Stuart was originally thought to have factor VII deficiency, but mixing his plasma with factor VII–deficient plasma corrected the abnormal clotting assay results. Patient Prower had multiple coagulation assay abnormalities, including a prolonged thromboplastin generation test and PT. The prevalence of symptomatic factor X deficiency is thought to be about 1 in 1 million persons (Table 139-1).

Factor X is a 58,000-Dalton protein that is the precursor of the protease factor Xa. Factor X may be activated by the factor VIIa/tissue factor complex or by the factor IXa/factor VIIIa complex (see Fig. 139-1, *A*). Factor Xa converts prothrombin to thrombin in the presence of factor Va and phospholipid and calcium ions; it also catalyzes the conversion of factor V to factor Va.

Congenital factor X deficiency is an autosomal recessive trait. Factor X–deficient mice die in utero or shortly after birth from hemorrhage, indicating the protein is necessary for viability. Humans with severe factor X deficiency (<1% of normal) probably have at least a trace of factor X in plasma. Most of the more than 100 known factor X gene mutations (representing more than 60 families) identified in factor X–deficient patients are missense mutations (www.isth.org/default/index.cfm; www.hgmd.org). Many are CRM+ variants. A classification system based on clotting, chromogenic, and immunologic assays has been proposed. Type I deficiency includes CRM– mutations, including patient Stuart (homozygous for Val298Met). Type II deficiency includes CRM+ variants lacking activity and includes patient Prower (compound heterozygote for Arg287Trp and Asp282Asn). Type III deficiency is composed of mutations that affect specific aspects of factor X/Xa function. Within type III deficiency are variants that are activated by Russell Viper venom but are defective in activation by factor VIIa/tissue factor or factor IXa/VIIIa (e.g., Factor X Friuli [Pro343Ser]), variants defective only in activation by factor VIIa/tissue factor (e.g., Factor X Padua [Arg251Trp] or Vorarlberg [Gla14Lys and Glu102Lys in the same factor X gene]), variants defective only in activation by factor IXa/VIIIa (factor X Melbourne and factor X Roma [Thr358Met]), and variants with higher activity in chromogenic assays than clotting assays. Factor X deficiency can be inherited with deficiencies of other vitamin K–dependent proteins (see Combined Deficiency of Vitamin K–dependent Proteins) and in combination with factor VII deficiency as a result of loss of both genes due to a chromosome 13 q34 deletion.

Acquired factor X deficiency occurs with warfarin therapy, vitamin K deficiency, liver disease, and DIC, all of which also reduce the levels of other coagulation factors. Factor X deficiency has been reported with malignancy, infections, and medication. There are rare reports of acquired factor X inhibitors. Acquired factor X deficiency may accompany systemic amyloidosis, occurring in 8.7% of patients with AL amyloidosis in one study, but rarely in secondary (AA) amyloidosis. Factor X binds to amyloid fibrils, which reduces the plasma half-life of the protein. Distinguishing this type of factor X deficiency from the inherited disorder is based on the clinical setting and evidence of poor clinical response to infusion of factor X–containing products in amyloidosis patients.

A classification system for factor X deficiency has been proposed based on factor X activity (severe, <1%; moderate, 1% to 5%; mild, 6% to 10%). Bleeding in factor X deficiency is severe and occurs earlier in life in patients with the lowest plasma levels. There is an impression that factor X–deficient patients bleed more severely than patients with other rare congenital coagulopathies. In a series of 102 factor X–deficient patients, the most frequent symptom was easy bruising (55%) followed by hematomas (43%).[18] Epistaxis and hemarthrosis were common. Intracranial hemorrhage occurred in 21%

and was particularly prevalent in patients with the Gly380Arg, IVS7-1G>A, and Tyr163delAT mutations. Among homozygotes, hemarthrosis was the most common symptom, and all homozygous women suffered from menorrhagia. Umbilical stump bleeding occurred in 28% of newborns. Mildly affected persons (activity >15%) may have increased bruising or bleeding with trauma. Although most heterozygotes are asymptomatic, as many as one-third have excessive bleeding from mucous membranes with invasive procedures or with childbirth.[19]

Because factor X is the first coagulation protease in the common pathway (see Fig. 139-1, *B*), its deficiency typically prolongs the PT and PTT and must be distinguished from deficiencies of fibrinogen, prothrombin, and factor V, which are associated with similar test results. Definitive diagnosis and determination of severity are established using a modified PT or PTT assay with factor X–deficient plasma. As discussed earlier, some factor X variants preferentially prolong either the PT or the PTT. Congenital factor X deficiency cannot be distinguished from acquired deficiency associated with amyloidosis in the coagulation laboratory, because factor X-dependent assays correct after mixing with normal plasma in both conditions. The absence of a lifelong bleeding disorder, findings of a serum M-protein, signs of amyloidosis, and histologic confirmation of amyloid in tissues point toward AL amyloidosis. A poor response to factor X infusion in the absence of an inhibitor distinguishes the two conditions.

Factor X–deficient patients are treated with FFP or PCC for most bleeding episodes (see Table 139-2). A trough level of 10% to 20% is usually sufficient for hemarthroses and soft tissue bleeding. The half-life of factor X is ≈20 to 40 hours. FFP administered as a loading dose of 10 to 20 mL/kg followed by 3 to 6 mL/kg every 12 to 24 hours will usually keep trough levels above 10% to 20%. Higher factor X levels may be required for severe bleeding or surgery, and accumulation of factor X in plasma can be achieved by increasing the transfusion frequency to every 12 hours. PCC with a factor X/IX ratio of ≈1 : 1 will increase plasma factor X levels by 1.5% for each factor IX unit/kg body weight. A dose of 15 to 20 factor IX units/kg daily or every other day has been suggested for major surgery. Risk for thromboembolism and DIC is a concern when using PCC, and it is recommended that plasma factor X levels not exceed 50% of normal, unless absolutely necessary. Plasma exchange has been used successfully to increase plasma factor X levels in pregnant women before delivery. For patients with severe factor X deficiency and recurrent hemorrhage, prophylactic PCC infusion is effective in preventing bleeding. Minor bleeding episodes can be treated with local measures and/or ε-amino caproic acid. Cryoprecipitate lacks factor X, and DDAVP infusion does not affect factor X levels and should not be used. A factor X concentrate is under investigation in the United States and Europe and may become the treatment of choice. As with prothrombin deficiency, there are no reports of acquired alloantibody inhibitors to factor X after replacement therapy is given to congenitally deficient patients, consistent with the concept that these patients have trace amount of plasma factor X at baseline.

Patients with acquired factor X deficiency and amyloidosis usually respond poorly to infusion of products containing factor X. Treatment may involve chemotherapy, splenectomy, plasma exchange, PCC, and/or activated factor VIIa. The optimal hemostatic management for invasive procedures has not been determined, but in one series complications occurred in only 13% of procedures, and there was a poor correlation between the risk for bleeding and factor X levels.

FACTOR XI DEFICIENCY (OMIM 264900)

In 1953, Rosenthal and colleagues described three members of a family with abnormal hemostasis, prolonged time to clot formation in a glass tube, and a normal PT. In mixing studies, patient plasma shortened the clotting times of hemophilia A and B plasmas, indicating that the missing factor was distinct from factors VIII and IX. Unlike the X-linked hemophilias, the new disorder (sometimes referred to as hemophilia C) was transmitted as an autosomal trait. The missing factor was called *plasma thromboplastin antecedent* and subsequently designated *factor XI*. Estimates place the incidence of factor XI deficiency at 1 per million (see Table 139-1), although some suggest this would be higher if symptomatic cases with mild deficiency were included. Severe factor XI deficiency (<20% of normal plasma level) is common in persons of Ashkenazi Jewish ancestry (incidence of 1 in 450).[20-22]

Factor XI is the precursor of the 160,000-Dalton protease factor XIa. The protein is a dimer of identical polypeptides. This unusual feature has implications for inheritance patterns in factor XI deficiency. Factor XI is activated by factor XIIa in the PTT assay (see Fig. 139-1, *B*). However, factor XI must be activated by factor XII-independent processes in vivo because factor XII deficiency does not cause abnormal bleeding. Factor XI can also be activated by thrombin or factor XIa. Factor XIa contributes to clotting by activating factor IX (see Fig. 139-1, *A*).

Factor XI deficiency in the Jewish population and in many non-Jewish patients is an autosomal recessive condition.[20-22] Two point mutations account for more than 90% of abnormal factor XI alleles in Ashkenazi Jews. The nonsense mutation Glu117Stop encodes a truncated protein, and homozygotes lack factor XI protein in their plasma. The missense mutation Phe283Leu causes a defect in dimer formation, resulting in poor secretion. Phe283Leu homozygotes have ≈10% of normal plasma factor XI activity, and the plasma protein is dimeric. Compound heterozygotes for Glu117Stop and Phe283Leu have activity of ≈3%, whereas heterozygotes for either mutation have activities of 50% to 60%. The allele frequencies of Glu117Stop and Phe283Leu in Ashkenazi Jews (0.0217 and 0.0254, respectively) indicate a carrier frequency for an abnormal factor XI allele of ≈5% in this population. Although Phe283Leu occurs primarily in Jews of European ancestry and may be of relatively recent origin, Glu117Stop is at least 2500 years old and is found in Jews from different ethnic backgrounds, as well as in non-Jewish patients.

Since the discovery of Glu117Stop and Phe283Leu, more than 200 human factor XI gene mutations have been identified. Although most are unique to specific patients or families, several mutations are more widespread with evidence of founder effects. Cys38Arg has an allele frequency of ≈0.5% in French Basques, Cys128Stop accounts for ≈10% of abnormal factor XI alleles in Great Britain, and Gln-88Stop is present in several families from Nantes, France. In most deficient patients, factor XI activity and antigen are comparably reduced (CRM−deficiency). A three-category scheme has been proposed for classifying CRM−factor XI deficiency. The first category contains mutations that prevent protein synthesis (e.g., Glu117Stop), whereas mutations in the second category interfere with dimer formation (e.g., Phe283Leu). Inheritance in both categories follows a recessive pattern, because mutant polypeptides do not interfere with the product of the normal allele in a heterozygote. The third category includes mutations that impair secretion but do not prevent dimer formation (e.g., Gly400Val). In heterozygotes, mutant and wild type polypeptides can form nonsecretable dimers, trapping normal protein in the cell (dominant negative effect). This may account for families in which severe to moderate factor XI deficiency appears to be a dominant trait. CRM+ factor XI mutations are rare, and they usually involve catalytic defects (e.g., Gly555Glu and Thr575Met). Factor XI Ser248Asn has normal activity in a PTT assay but binds poorly to platelets, possibly explaining the bleeding disorder associated with the mutation.

Factor XI levels decrease in liver disease and DIC but are not affected by vitamin K deficiency or warfarin therapy. Mild to moderate factor XI deficiency occurs in ≈25% of patients with Noonan syndrome and is also common in carbohydrate-deficient glycoprotein syndrome, a group of inherited disorders involving defects in glycosylation of secretory glycoproteins. Antibody inhibitors to factor XI are relatively common after replacement in deficient patients, with one-third of Glu117Stop homozygotes developing inhibitors, often after a single exposure to plasma.

Significant bleeding in severe factor XI deficiency is usually injury-related and is most frequent in tissues with robust fibrinolytic activity, such as the oral cavity, tonsils, and urinary tract.[20-22] Injury to these areas causes excessive bleeding in two-thirds of patients, regardless of genotype. Bleeding with injury at other locations is less frequent and tends to occur in those with the lowest factor XI levels.[20-23] Thus Glu117Stop homozygotes have more bleeding than Phe283Leu homozygotes. Excessive bleeding with skin laceration, circumcision, appendectomy, and orthopedic surgery is infrequent; and spontaneous bleeding (except for menorrhagia) is uncommon. Bleeding may start at the time of injury or be delayed by hours, and oozing from tooth extraction sites may persist for days. Bleeding correlates relatively poorly with plasma factor XI activity. Patients with severe deficiency may not bleed excessively, even during surgery without treatment, and a patient may exhibit different bleeding tendencies over time. Opinions differ regarding the propensity of patients with mild deficiency (20% to 50% of normal level) to bleed. Some studies describe minimal bleeding with tooth extraction, tonsillectomy, nasal surgery, and urologic surgery, whereas others report difficulty distinguishing severe from mild deficiency on clinical grounds. In a study of 45 families with factor XI deficiency, the odds ratios for excessive bleeding were 13.0 and 2.6 for homozygotes and heterozygotes, respectively. Thus mild factor XI deficiency may confer a slightly increased risk for bleeding but significantly less than the risk with severe deficiency.

In the PTT assay, factor XI is bound to the contact surface through high-molecular-weight kininogen and is activated by factor XIIa (see Fig. 139-1, *B,* and Fig. 139-3). Factor XIa, in turn, activates factor IX. Therefore factor XI deficiency prolongs the PTT, but not the PT. Diagnosis and severity are established by a modified PTT assay using factor XI–deficient plasma. The PTT is often normal in heterozygotes.

Perioperative therapy should be individualized for factor XI–deficient patients (see box on Treating Factor XI–Deficient Patients). Those requiring replacement may be treated with FFP or factor XI concentrate (Hemoleven or FXI concentrate) (see Table 139-2). The concentrates are effective in preventing bleeding with invasive procedures. Hemoleven received orphan drug-designation from the United States Food and Drug Administration in 2007. In the 1990s, use of factor XI concentrates was associated with thrombosis and evidence of DIC, primarily in older patients with cardiovascular disease receiving doses higher than 30 units/kg. To reduce procoagulant potential, current concentrates contain antithrombin and heparin, with or without C1-inhibitor. It is recommended that the factor XI level be raised no higher than 60% of the normal level with concentrates. Cryoprecipitate does not contain factor XI. The half-life of factor XI is 45 to 52 hours, facilitating daily or every-other-day administration. For major surgery or procedures involving the oropharynx or urinary tract, patients with severe deficiency should be treated to keep factor XI levels at ≈40% of normal for 7 days postoperation.[20-22] Minor surgery can be treated for 5 days to keep levels at ≈30% of normal. Circumcision, orthopedic surgery, and appendectomy carry a low bleeding risk, and replacement can be withheld unless bleeding occurs.[23] A similar "wait and see" approach has been proposed for factor XI–deficient women during labor and delivery, which are associated with a relatively low (≈20%) rate of excessive bleeding. However, others advocate replacement for childbirth. Dental procedures such as tooth extraction do not require FFP and should be covered with antifibrinolytic therapy. Patients with factor XI levels higher than 40% of normal do not require replacement for surgery. The effectiveness of DDAVP in mild factor XI deficiency is not established, but there are reports that factor XI levels increase in response to this drug. Factor XI–deficient patients with inhibitors do not usually have increased spontaneous bleeding. Recombinant factor VIIa has been used successfully for major surgery in factor XI–deficient patients with and without inhibitors and to cover epidural block in deficient women during labor and delivery.

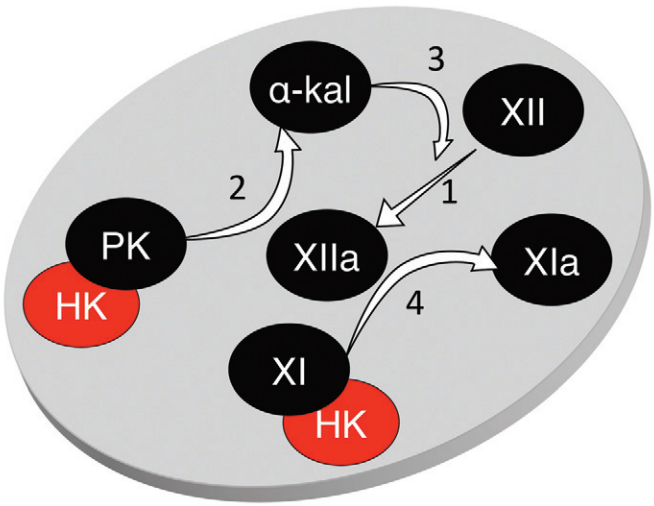

Figure 139-3 CONTACT ACTIVATION REACTIONS. In the PTT assay, contact activation is initiated by activation of factor XII (XII) to α-factor XIIa (XIIa) (reaction 1) when plasma is exposed to a negatively charged surface *(gray disk).* Factor XIIa converts prekallikrein (PK) to the active protease α-kallikrein (reaction 2), and α-kallikrein reciprocally activates additional factor XII (reaction 3). Factor XIIa initiates coagulation through conversion of factor XI (XI) to factor XIa (XIa) (reaction 4). Note that PK and factor XI require high-molecular-weight kininogen (HK) to bind properly to the negatively charged surface. Factor XIa ultimately promotes thrombin generation and fibrin clot formation through activation of factor IX (see Fig. 139-1).

DEFICIENCIES OF THE CONTACT FACTORS: FACTOR XII, PREKALLIKREIN, AND HIGH-MOLECULAR-WEIGHT KININOGEN

Factor XII, prekallikrein, and high-molecular-weight kininogen are required for normal activation of factor XI in the "contact phase" that initiates coagulation in the PTT assay (see Fig. 139-1, *B,* and Fig. 139-3). Patients with a deficiency in any one of these proteins have a prolonged PTT, but do not have abnormal hemostasis, even with major surgery or injury. Therefore these proteins either do not participate in hemostasis, or redundant mechanisms compensate for their absence. No specific therapy is required to prepare deficient patients for invasive procedures. However, it is important to distinguish factor XII, prekallikrein, or high-molecular-weight kininogen deficiency from deficiencies of factors VIII, IX, or XI, which also prolong the PTT, but cause abnormal hemostasis.

Factor XII Deficiency (OMIM 234000)

In 1955, Ratnoff and Colopy described three asymptomatic individuals with a novel abnormality of surface-induced coagulation. The missing plasma component was called *Hageman factor* (after the index case) and later designated *factor XII.* The incidence of severe factor XII deficiency is not known, because some deficient persons almost certainly go undiagnosed. Moderate to severe factor XII deficiency was reported in 1.5% to 3.0% of healthy blood donors. This unexpectedly high prevalence may be partly explained by anti–factor XII or antiphospholipid antibodies that interfere with factor XII activity assays.

Factor XIIa, the activated form of factor XII, is an 80,000-Dalton protease that activates factor XI and prekallikrein in the contact phase of the PTT assay (see Fig. 139-3). A C/T polymorphism in the 5′-untranslated region of the factor XII gene (referred to as 46C/T [or -4C/T]) strongly influences plasma factor XII levels, with the 46T allele associated with lower levels compared with 46C. The frequency of 46T is high (73%) in East Asians (compared with 20%

Treating Factor XI–Deficient Patients

When preparing patients with severe factor XI deficiency (plasma factor XI level <20% of normal) for an invasive procedure, it is important to keep in mind that (1) a negative bleeding history does not indicate a low risk with subsequent procedures, (2) certain procedures are associated with lower bleeding risks than others, and (3) patients with very low factor XI levels (<1%) often develop neutralizing inhibitors with replacement therapy. These observations have led to refinements in treatment recommendations that limit exposure to factor XI by targeting replacement therapy to certain clinical situations. Replacement therapy to reach appropriate target levels may be required for patients with mild factor XI deficiency (levels of 20% to 40% of normal) undergoing certain types of procedures.

Antiplatelet drugs should be stopped 1 week before surgery. The prothrombin time and platelet count should be normal, and the possibility of coexisting hemostatic abnormalities thoroughly investigated. Patients with factor XI levels greater than 40% to 45% generally do not experience bleeding, and a history of excessive bleeding in such an individual suggests other hemostatic abnormalities are present. If the patient has been exposed to factor XI in the recent past, the possibility that a neutralizing inhibitor is present should also be considered.

Factor replacement is required for most major surgery in factor XI–deficient patients and should be initiated before the procedure. Surgery on the oropharynx, nasopharynx, or urinary tract should be treated with FFP or factor XI concentrate to keep the plasma level at ≈40% of normal for at least 7 days. A similar strategy is appropriate for neurosurgery, head and neck surgery, cardiothoracic procedures, and major abdominal or pelvic surgery. For nasal surgery and oral procedures such as tonsillectomy, supplementing replacement therapy with antifibrinolytic therapy should be strongly considered. For prostatectomy and other surgery on the lower urinary tract, flushing the bladder with saline containing an antifibrinolytic agent may be beneficial. Minor surgery can be treated with replacement to maintain levels of 30% for 5 days.

A "wait and see" strategy, in which replacement is withheld unless bleeding occurs, appears to be appropriate for procedures such as circumcision, appendectomy, and some orthopedic surgery, as well as with normal vaginal deliveries. There are insufficient data to determine whether epidural anesthesia is safe in the absence of factor coverage, and replacement therapy should be used.

Factor XI concentrates are likely to become more popular in the near future for treating factor XI–deficient patients, and it is important to recognize that use of earlier versions of these preparations were associated with a high (10%) incidence of thromboembolism. The majority of thrombotic events occurred in older adult patients with preexisting cardiovascular disease, and these patients should probably not be treated with factor XI concentrate unless absolutely necessary. For other patients, the concentrates offer an effective form of treatment that requires a much smaller volume of infusion than does therapy with FFP.

Alternatives to factor replacement are recommended in several situations. Tooth extraction or skin biopsies can be managed with antifibrinolytic drugs alone (ε-amino caproic acid 5 to 6 g every 6 hours or tranexamic acid 1 g every 6 hours), starting 12 hours before the procedure and continuing for 7 days. Fibrin glues can be used in place of fibrinolytic therapy for skin biopsy or resection of skin lesions. Recombinant factor VIIa has been used successfully in factor XI–deficient patients with and without factor XI inhibitors and may be appropriate in situations in which exposure to plasma products needs to be limited.

Patients with factor XI deficiency can experience thromboembolic episodes. Aspirin or clopidogrel can be used in factor XI–deficient patients with myocardial infarction or other manifestations of atherosclerosis, whereas atrial fibrillation or venous thromboembolism should be treated with warfarin, with the goal of not allowing the INR to exceed 2.5.

in Caucasians), who have lower factor XII levels than other ethnic groups. Factor XII activity and antigen are usually reduced in parallel in deficient individuals, and circulating dysfunctional variants are rare.

Several factor XII gene mutations have been identified (www.hgmd.org). Factor XII deficiency is not associated with spontaneous or excessive posttraumatic bleeding, and most cases are identified by the incidental finding of a prolonged PTT. There is conflicting literature regarding an association between factor XII deficiency and thrombosis. Two recent studies reported an inverse relationship between plasma factor XII levels within the broad normal range and the risk for cardiovascular events. However, other work indicates that the increased risk does not apply to persons with severe factor XII deficiency or that low factor XII levels are more of a risk marker rather than a contributor to thrombosis. A metaanalysis of studies examining the 46C/T factor XII gene polymorphism, the major genetic determinant of plasma factor XII level, suggests that the correlation between the polymorphism and venous thrombosis or myocardial infarction, if present, is weak. Reports have linked low factor XII levels to pregnancy loss or failure of in vitro fertilization. Of interest, factor XII–deficient mice do not display an abnormality in reproduction. It is possible that antibodies that interfere with factor XII function, rather than true deficiency, are responsible for pregnancy-related complications in humans.

Factor XII undergoes autoactivation when exposed to the contact surface added to plasma to initiate clotting in the PTT assay. Factor XIIa activates prekallikrein to α-kallikrein, which reciprocally activates additional factor XII (see Fig. 139-3). Factor XIIa also activates factor XI to XIa. In severe factor XII deficiency, the PTT is very long. Definitive diagnosis is established using a modified PTT assay with factor XII–deficient plasma. Antiphospholipid antibodies may disproportionately affect factor XII measurements in PTT-based assays. In addition, factor XII antibodies are present in up to half of plasmas with antiphospholipid antibodies and may account for many cases of presumed mild deficiency.

Prekallikrein Deficiency (OMIM 229000)

In 1965, Hathaway and coworkers reported on members of a family with long plasma clotting times that corrected on prolonged incubation with glass. They did not have a history of excessive bleeding. The missing plasma component, initially called *Fletcher factor* after the index cases, was subsequently shown to be prekallikrein. Severe prekallikrein deficiency appears to be rare; however, mild cases may be missed because a low level of prekallikrein activity is often sufficient to bring many PTT assays into the normal range.

Prekallikrein is the 95,000-Dalton precursor of the protease α-kallikrein. Prekallikrein deficiency is an autosomal trait, presenting in the homozygous or compound heterozygous forms with plasma levels less than 1% of normal. CRM− variants, which account for about half of cases, are common in Caucasian and Japanese patients, whereas most black patients are CRM−. Few prekallikrein gene mutations have been identified (www.hgmd.org). Partial deficiency (10% to 50%) may be seen in patients with severe high-molecular-weight kininogen deficiency, likely due to increased catabolism or clearance because prekallikrein circulates in complex with high-molecular-weight kininogen. Severe prekallikrein deficiency presents as a prolongation of the PTT in a person without a history of excessive bleeding. Although thrombotic events have been described in deficient patients, it is not clear that the deficiency contributed to thrombosis. Indeed, recent studies in mice indicate that reducing prekallikrein levels can attenuate thrombus formation.

In the PTT, prekallikrein is converted to α-kallikrein by factor XIIa, which in turn reciprocally activates factor XII (see Fig. 139-3). Severe prekallikrein deficiency causes a prolonged PTT, and the diagnosis is confirmed using a modified PTT with prekallikrein–deficient plasma. The prolonged PTT in prekallikrein deficiency may be shortened by prolonged incubation with the contact reagent, which allows factor XII sufficient time to activate independently of prekallikrein. This distinguishes prekallikrein deficiency from deficiencies of factors VIII, IX, XI, XII, and high-molecular-weight kininogen, in which the prolonged PTT does not correct with prolonged incubation. PTT reagents using the contact activator ellagic acid are relatively insensitive to prekallikrein and may fail to detect some deficient patients.

High-Molecular-Weight Kininogen Deficiency (OMIM 228960)

In 1974, Schiffman and Lee reported that a plasma factor distinct from prekallikrein was required for factor XI activation by factor XIIa. In 1975, three asymptomatic patients from three separate families who appeared to lack the unknown factor were described with in vitro abnormalities of coagulation, fibrinolysis, and kinin generation. The condition, originally named for the affected families (Fitzgerald trait, Williams trait, and Flaujeac trait), was subsequently determined to be due to high-molecular-weight kininogen deficiency. The disorder appears to be very rare.

High-molecular-weight kininogen is a 110,000-Dalton protein that contains the vasoactive peptide bradykinin. Prekallikrein and factor XI circulate in complex with high-molecular-weight kininogen. Low-molecular-weight kininogen and high-molecular-weight kininogen are products of a single kininogen gene; however, low-molecular-weight kininogen does not play a role in coagulation in vitro. High-molecular-weight kininogen deficiency is an autosomal recessive trait. Depending on the genetic abnormality (www.hgmd.org), patients may have isolated high-molecular-weight kininogen deficiency or combined high-molecular-weight and low-molecular-weight kininogen deficiency. High-molecular-weight kininogen–deficient patients are usually identified by the incidental finding of a prolonged PTT, and they do not bleed excessively.

In the PTT assay, high-molecular-weight kininogen facilitates binding of prekallikrein and factor XI to the contact surface, thereby enhancing their activation by factor XIIa (see Fig. 139-3). Severe deficiency is characterized by a very prolonged PTT, and definitive diagnosis is established using a modified PTT with high-molecular-weight kininogen–deficient plasma. Partial prekallikrein deficiency is common in severe high-molecular-weight kininogen deficiency, likely due to increased catabolism of prekallikrein when it is not in complex with high-molecular-weight kininogen.

FACTOR XIII DEFICIENCY (OMIM 134570 [A SUBUNIT] AND 134580 [B SUBUNIT])

In 1944, Robbins demonstrated that fibrin formed from purified components was soluble in weak acid, whereas fibrin formed in the presence of serum or plasma was not. He proposed that a fibrin-stabilizing factor was present in plasma. In 1960, Duckert and colleagues described the first patient with deficiency of fibrin-stabilizing factor, which was subsequently designated *factor XIII*. The incidence of severe factor XIII deficiency is estimated at 1 in 2 million (see Table 139-1).[24-26]

Factor XIII in blood is distributed between plasma and platelets, with a small amount in monocytes. The plasma protein is a 330,000-Dalton tetramer composed of two catalytic A subunits and two carrier B subunits. Factor XIII in platelets, monocytes, and placenta has only A subunits. The A subunit in plasma appears to be synthesized primarily in hematopoietic cells, whereas the B subunit comes from the liver. Factor XIII is converted to the transglutaminase factor XIIIa by thrombin, and it catalyzes formation of γ-glutamyl-ε-lysyl bonds between fibrin monomers (see Fig. 139-1, *A*), resulting in a fibrin mesh that is resistant to dissolution in mild acids and urea. Factor XIIIa also cross-links fibrin to plasma, extracellular matrix, and cytoskeletal proteins, facilitating clot adherence to an injury site. Congenital factor XIII deficiency is an autosomal recessive condition. The currently recommended classification scheme recognizes factor XIII-A and factor XIII-B deficiencies. Factor XIII-A deficiency is divided into type I (quantitative) and type II (qualitative) deficiencies. Although earlier systems included a combined A and B deficiency category, low levels of the A subunit in these cases was the result of rapid clearance because of the absence of the B subunit.

Most cases of congenital factor XIII deficiency are due to mutations in the gene for the A subunit, with less than 5% in the B subunit gene.[25] More than 100 different mutations have been reported in the factor XIII-A gene, with less than 20 in the factor XIII-B gene. (www.isth.org/default/index.cfm; www.hgmd.org; www.f13-database.de). The incidence of factor XIII mutations affecting plasma activity is probably higher than suspected, considering that screening test abnormalities occur mostly in those with severely decreased plasma activity (<5% of normal). A few mutations show evidence of a founder effect, with the IVS5–1 G>A splice-site defect and Arg661Stop nonsense mutations each identified in 10 apparently unrelated individuals.

Plasma factor XIII levels decrease in DIC and liver disease. However, significant deficiency is rare in liver disease and may indicate a poor prognosis. Acquired deficiency has been reported in leukemia, Crohn disease, ulcerative colitis, and Henoch-Schönlein purpura, but levels are usually above 30% of normal and replacement is not required. Alloantibodies to factor XIII induced by replacement therapy are relatively rare in factor XIII–deficient patients. Neutralizing autoantibodies that block the activation, activity, or fibrin binding capacity of the factor XIII-A subunit, or that enhance factor XIII clearance from plasma, have been reported in older adults, in patients with systemic lupus erythematosus and lymphoproliferative disorders, and with medications such as isoniazid, penicillin, procainamide, phenytoin and practolol. An autoantibody to the B subunit that developed in a patient with lupus markedly enhanced clearance of the protein from plasma and was associated with life-threatening bleeding.

Delayed bleeding from the umbilical stump occurs in 80% to 90% of newborns with severe factor XIII deficiency and is considered a diagnostic feature of the disorder.[24-26] Ecchymoses, soft tissue hematomas, and prolonged bleeding with trauma are common, and recurrent soft tissue bleeding may lead to formation of hemorrhagic cysts (pseudotumors). Hemarthroses is less frequent than in factor VIII or IX deficiency. Bleeding that is delayed 12 to 36 hours postinjury is characteristic of factor XIII deficiency, although hemorrhage can be immediate in some cases. Bleeding at the time of invasive procedures may be minimal, but delayed hemorrhage often occurs. Intracranial bleeding is more frequent in factor XIII deficiency than in other inherited coagulation disorder, with an incidence as high as 30%, which justifies prophylactic replacement. Delayed wound healing has been observed in deficient patients, possibly related to a defect in angiogenesis. Recurrent spontaneous abortions occur with most pregnancies in untreated factor XIII–deficient women,[27] possibly due to abnormal formation of the cytotrophoblastic shell and poor attachment of the placenta to the uterus. The problems just described are recognized complications in patients with factor XIII levels less than 5% of normal. The issue of excessive bleeding in patients with milder factor XIII deficiency is more controversial. In at least two studies, patients heterozygous for factor XIII deficiency reported excessive bleeding. These studies lacked control groups, so it is difficult to determine whether the mild deficiency was responsible for symptoms. However, experience with pregnant women with severe factor XIII deficiency shows that the factor XIII level needs to be higher than 10% to reliably prevent pregnancy loss, indicating that clinically significant problems can occur in patients with levels higher than 5% of normal.

The PT and PTT measure time to fibrin clot formation; they do not assess clot stability. Results of these assays are therefore normal in factor XIII–deficient patients. Clots formed in plasma lacking

factor XIII are soluble in 5 M urea or 1% monochloroacetic acid, whereas normal clots are stable for at least 24 hours. Solubility in 5 M urea (urea clot stability assay) is frequently used to screen for factor XIII deficiency or inhibitors. The assay is relatively insensitive to factor XIII deficiency and identifies only patients with factor XIII levels less than 5% of normal. Clots from plasma lacking α_2-antiplasmin can also show increased solubility in this assay, and can be identified with specific assays. Chromogenic assays for measuring factor XIIIa activity are commercially available and should strongly be considered as replacements for the urea clot lysis assay. These assays can also be used to detect and quantify neutralizing factor XIII inhibitors, using a mixing method with normal plasma.

The plasma half-life of factor XIII is 10 to 14 days,[20-22] facilitating prophylactic replacement therapy to prevent intracranial bleeding. Although some consider a plasma level of ≈5% adequate for hemostasis,[28] others suggest that levels in excess of 10% are required to significantly reduce bleeding risk. Both FFP and cryoprecipitate contain factor XIII; however, the factor XIII concentrate Fibrogammin P (marketed as Corifact in the United States; see Table 139-2) is the preferred replacement preparation.[24-29] Recombinant factor XIII has also undergone evaluation, and is awaiting approval. Fibrogammin P contains factor XIII purified from human plasma and is pasteurized. A regimen of 40 units/kg every 4 weeks is recommended for prophylaxis. A dose of 20 to 30 units/kg/day should be used with major surgery to keep the plasma activity higher than 20% to 50% of normal. For minor surgery, 10 to 20 units/kg/day for 2 to 3 days is sufficient, whereas bleeding episodes can be treated with 10 to 30 units/kg/day depending on the severity of the hemostatic abnormality. In pregnancy, factor XIII replacement should be started early, preferably before gestational week 5, because decidual bleeding from implantation will occur without replacement. The optimal plasma factor XIII concentration in pregnancy is not established, but at least 10% of normal is recommended. This can be achieved by infusing 250 units of concentrate every 7 days through week 22 of gestation, and 500 units per week for the remainder of pregnancy, with a bolus of 1000 units during labor. Although factor XIII concentrate is preferred for prophylaxis or treatment of acute bleeding, if it is not available, FFP (10-20 mL/Kg every 4 to 6 weeks) or cryoprecipitate (1 unit for every 10 to 20 kg body weight every 3 to 4 weeks) can be used.

CONGENITAL DEFICIENCIES INVOLVING MULTIPLE COAGULATION FACTORS

Numerous cases of congenital deficiencies of more than one coagulation factor have been described. Although most of these likely represent chance coinheritance of distinct deficiency states, several represent familial syndromes (see Table 139-3). Such syndromes are likely caused by abnormalities in intracellular processing of factors (e.g., type 1 deficiency) or alterations in the structure/activity of multiple factors due to abnormalities in posttranslational modification (e.g., type 3 deficiency). It must be remembered that common nonspecific inhibitors such as lupus anticoagulants interfere with coagulation assays and can lead to erroneous interpretations when they suggest multiple factor deficiencies (see box on Laboratory Testing in Rare Coagulation Factor Deficiencies). Similarly, potent inhibitors directed at a single coagulation factor (e.g., factor VIII) may occasionally interfere with assays for other factors. Two familial multiple factor deficiency states, combined factor V and VIII deficiency (type 1) and deficiency of vitamin K dependent factors (type 3), have been well characterized.

Combined Factor V and Factor VIII Deficiency (OMIM 227300)

Combined factor V and factor VIII deficiency was first reported in 1954. The familial form is an autosomal recessive trait caused by mutations in either the LMAN1 (mannose-binding lectin, formerly ERGIC-53) or MCFD2 (multiple combined factor deficiency protein) gene (www.isth.org/default/index.cfm). These proteins form a cargo receptor that is required for transport of factors V and VIII from the endoplasmic reticulum (ER) to the ER-Golgi intermediate compartment. Although the incidence of this disorder is thought to be 1 in 1 million persons, the allele frequency is particularly high (≈1%) in Tunisian Jews originating from a community on the island of Djerba.

Table 139-3 Combined Familial Deficiency States

Type	Deficient Factors	OMIM Designation	Underlying Cause
1	V and VIII	227300	Mutations in LMAN1 or MCFD2 genes
2	VIII and IX	134510	Unknown
3	II,VII, IX, X, protein C, and protein S	277450 (γ-glutamyl carboxylase) 607473 (vitamin K oxidoreductase)	Mutations in γ-glutamyl carboxylase (GGCX) or vitamin K epoxide reductase complex subunit 1 genes
4	VII and VIII	134430	Unknown
5	VIII, IX, and XI	134520	Unknown
6	IX and XI VII and X	134540	Unknown Gene deletion 13q34

OMIM, Online Mendelian Inheritance in Man.

Deficiency of either LMAN1 or MCFD2 activity causes a partial defect in factor V and factor VIII secretion, lowering plasma levels to ≈5% to 30% of normal. The mutation in Tunisian Jews is a T-to-C transition at a donor splice site in intron 9 of the LMAN1 gene. A history of consanguinity, co-segregation of the factor deficiencies, and similar reductions in factor V and VIII favor the familial disorder. Homozygotes or compound heterozygotes bleed primarily after trauma, although epistaxis, gingival bleeding, easy bruising, and menorrhagia are common. Non–trauma-related hemarthrosis may occur in 20% of patients, but bleeding from the GI tract or intracranial hemorrhage is less common. Postpartum hemorrhage occurs in most affected women, and invasive procedures, including dental extraction, are usually accompanied by excessive bleeding without replacement therapy. The disorder is associated with a prolonged PT and PTT (see Fig. 139-1, *B*). Isolated factor V deficiency also follows this pattern so it is recommended that patients with factor V deficiency have factor VIII levels measured to ensure that combined deficiency is not overlooked. Patients with mucosal bleeding and menorrhagia may respond to antifibrinolytic therapy. For more significant bleeding, or in preparation for surgical procedures or tooth extraction, a combination of FFP and factor VIII concentrate should be used. DDAVP can raise factor VIII, but not factor V levels. Trough levels of ≈50% for factor VIII and 25% for factor V have been recommended for surgery. Plasma exchange may be used to raise factor V levels in situations in which volume overload from large volumes of FFP is a concern.

Combined Deficiency of Vitamin K–Dependent Proteins (OMIM 277450 and 607473)

In 1966, McMillan and Roberts described a newborn girl with a prolonged PT and PTT; low levels of prothrombin and factors VII, IX, and X; and no evidence of liver disease or malabsorption. She had a partial response to large doses of vitamin K. In subsequent cases, low protein C and protein S levels were also noted in association with mutations in the γ-glutamyl carboxylase (GGCX) gene. Although the condition is considered to be a rare autosomal recessive trait, severe bleeding has been reported in a neonate who was heterozygous for a GGCX mutation.

Laboratory Testing in Rare Coagulation Factor Deficiencies

When deficiency of a coagulation factor is being considered, it is important to remember that (1) acquired conditions causing multiple factor deficiencies are more common than congenital deficiency of a single factor and (2) common nonspecific inhibitors of coagulation, such as lupus anticoagulants and heparin, will interfere with coagulation factor assays. Unexplained prolongation of the PT or PTT should be evaluated in a qualified laboratory. If at all possible, the plasma should be from blood collected by venipuncture. In our experience, the common practice of collecting blood from central venous catheters/ports or peripheral intravenous catheters frequently introduces fluids or drugs that adversely affect clotting assays and may contribute to misdiagnosis. Some laboratories use the thrombin time assay to screen samples for possible contamination with heparin or direct thrombin inhibitors to avoid this pitfall.

The initial evaluation of a plasma sample with a prolonged PT or PTT should start by repeating the abnormal test on a mixture of patient and normal plasma to determine whether the prolonged clotting time is related to a clotting factor deficiency (clotting time becomes normal with mixing) or an inhibitor that neutralizes clotting factor activity (clotting time remains prolonged with mixing). The mixing study should be performed with and without prolonged incubation (2 hours), because some antibody inhibitors show a time-dependent pattern of inhibition. Slight (a few seconds) prolongation of the PT or PTT can be difficult to evaluate with a mixing study. We evaluate such samples with assays for lupus anticoagulants before measuring specific levels of coagulation factors.

The antibodies to clotting factors that most physicians are familiar with neutralize factor activity and generate abnormal results on a mixing study (i.e., mixing with normal plasma fails to correct the abnormal clotting time). However, it is important to recognize that nonneutralizing antibodies can also be associated with severe factor deficiency. These antibodies typically enhance clearance of the clotting factor from the plasma in vivo and will not be detected by a mixing study. A failure to respond to replacement therapy in the absence of a clearly measurable inhibitor suggests this diagnosis. In our practice, we have observed severe acquired deficiencies of prothrombin, factor X, factor XI, and factor XIII caused by nonneutralizing antibodies.

If the level of a vitamin K–dependent protein (prothrombin or factors VII, IX, or X) is low, levels of factor V and at least one other vitamin K–dependent factor should be determined. If multiple vitamin K–dependent factors are low and factor V is normal, a process affecting vitamin K is likely. If factor V is also low, liver disease or DIC should be considered. Tests for hepatic function (albumin) or injury (transaminases) can facilitate interpretation of the coagulation factor studies. Distinguishing DIC from liver disease can be difficult, because results of standard tests such as the PT, PTT, platelet count, and fibrinogen and D-dimer levels may be abnormal in both conditions. Measuring factor V and factor VIII may be useful in this situation, because both factors are often low in DIC, whereas factor VIII is normal or elevated in liver disease.

Patients with factor XI, factor XII, prekallikrein, or high-molecular-weight kininogen deficiency may require anticoagulation for thromboembolism or other indications. Assays based on contact activation such as the PTT or the activated clotting time cannot be used for monitoring therapy with heparin or direct thrombin inhibitors such as argatroban or lepirudin in these patients, because the baseline test result will be abnormal. Many hospital laboratories now measure heparin with chromogenic assays based on factor Xa inhibition. Specific assays for argatroban and lepirudin are less readily available. Alternatively, low-molecular-weight heparin, fondaparinux or one of the new oral thrombin or factor Xa inhibitors that do not require monitoring may be used in these situations.

Prothrombin; factors VII, IX, and X; proteins C and S; and the bone proteins osteocalcin and matrix Gla protein require γ-carboxylation of glutamic acid residues in their N-terminal Gla-domains. γ-Carboxylation is mediated by GGCX (which uses reduced vitamin K as a cofactor) and results in formation of vitamin K 2,3-epoxide, which must be reduced vitamin K epoxide reductase complex subunit 1 to replenish the vitamin K pool. Mutations in the GGCX (e.g., Arg394Leu; see www.hgmd.org) or VKORC1 (e.g., Arg98Trp) genes can impair this process and result in reduced levels (10% to 50% of normal) of all vitamin K–dependent proteins, resulting in a variable bleeding tendency that may be severe. Some patients have skeletal abnormalities resembling warfarin embryopathy, possibly due to reduced activity of vitamin K–dependent bone proteins. Vitamin K–dependent proteins are reduced in patients taking warfarin, in poisoning with rodenticides such as brodifacoum, and with vitamin K deficiency. The levels of these proteins are also low in liver failure, in conjunction with other proteins synthesized in the liver, and in malabsorption syndromes. An acquired antibody that resulted in fatal bleeding in a patient with a lymphoproliferative disorder bound to an epitope on the Gla domain of prothrombin and factors IX and X.

The low levels of prothrombin and factors VII, IX, and X cause prolongation of the PT and PTT. Protein C and protein S are also reduced. The abnormalities correct on mixing with normal plasma. Failure to do so suggests that a nonspecific inhibitor such as a lupus anticoagulant is interfering with the assay. Patients with deficiencies of vitamin K–dependent proteins should be evaluated for liver disease, malabsorption, and exposure to warfarin or rodenticides containing vitamin-K antagonists such as brodifacoum. Toxicology screens can identify these agents in blood long after ingestion because of their long half-lives. Some patients have adequate clinical response to vitamin K_1 (10 mg weekly), but others require unusually high doses. Nonresponders, or responders with significant bleeding episodes, can be treated with FFP or PCC.

CHAPTER 140

STRUCTURE, BIOLOGY, AND GENETICS OF VON WILLEBRAND FACTOR

Paula James and Natalia Rydz

von Willebrand factor (vWF) is an adhesive multimeric plasma glycoprotein that performs two major functions in hemostasis: it mediates platelet adhesion to injured subendothelium via glycoprotein 1bα (GP1bα), and it binds and stabilizes factor VIII (FVIII) in the circulation, protecting it from proteolytic degradation by enzymes. This important multifunctional protein was named after the Finnish physician, Dr. Erik von Willebrand, who first described von Willebrand disease (vWD) in 1926. In the original publication[1] he described a severe mucocutaneous bleeding problem in a family living on the Åland archipelago in the Baltic Sea. The index case, a young woman named Hjördis, bled to death during her fourth menstrual period at the age of 13. At least four other family members died from severe bleeding, and although the condition was originally referred to as *pseudohemophilia*, Dr. von Willebrand noted that in contrast to hemophilia, this condition affected both genders, with females typically being more severely affected. He also noted that affected individuals exhibited prolonged bleeding times despite normal platelet counts.

In the mid-1950s it was recognized that vWD was usually accompanied by a reduced level of FVIII activity and that the bleeding phenotype could be corrected by the infusion of normal plasma.[2] In the early 1970s the critical immunologic distinction between FVIII and vWF was made, and since that time significant progress has been made in our understanding of the molecular pathophysiology of this disorder. vWD is caused by qualitative or quantitative defects of vWF. Cloning and characterization of the vWF gene in the 1980s[3-6] has facilitated further investigation into the function of vWF and the genetic basis of vWD.

FUNCTIONS OF vWF

vWF is a multifunctional adhesive protein that plays an important role in both primary hemostasis and blood coagulation. In primary hemostasis, vWF initiates platelet adhesion at the site of endothelial injury, whereas in coagulation, vWF stabilizes FVIII in the circulation (Fig. 140-1).

Platelet Adhesion

At the site of endothelial injury, vWF secreted from local endothelial cells or recruited from the circulation adheres to exposed collagen. The most hemostatically important forms of collagen include types I, III, and VI, but vWF preferentially binds to type III collagen.[7] The interactions of vWF with collagen are predominately mediated by the A3 domain (See Figure 140-2). Once immobilized, vWF is subjected to the high shear rates of the arterial circulation and undergoes a conformational change that exposes the platelet GPIbα binding site within the A1 domain.[8] The high-affinity, rapid, and reversible interaction between vWF and GPIbα tethers platelets to the endothelium, where they roll until they are immobilized by integrin-mediated binding, which has slower binding kinetics. The Arg-Gly-Asp (RGD) sequence within the C1 domain also contributes to platelet adhesion by interacting with GPIIb-IIIa of activated platelets.[9]

FVIII Stabilization

vWF binds FVIII through the D'D3 domains and protects it from proteolytic degradation, thereby prolonging its half-life. In the absence of vWF, FVIII has a half-life of approximately 2 hours in contrast to a normal half-life of 12 to 20 hours when bound to vWF.[10]

BASAL vWF LEVELS

The normal level for vWF is highly variable and ranges from 50 to 200 IU/dL.[11] Factors that contribute to the variable vWF levels include ABO genotype (see section on ABO blood groups later), Secretor genotype, race, and age. Although plasma vWF concentrations have been reported to be approximately 20% higher in subjects homozygous for the Secretor (Se) allele as compared with those who are heterozygous,[12] studies exploring this relationship have yielded inconsistent results.[13] vWF levels in African Americans are 15% higher than those in whites.[14] Increased age has also been associated with higher vWF levels,[15,16] with studies suggesting that the levels may increase by as much as 15 to 17 units/mL per decade.[17] In addition, older age is associated with lower ADAMTS13 activity,[18] which together with the higher vWF levels, may contribute to the hypercoagulability that can be seen in older adults.

Within subjects, vWF levels often vary over time as a result of β-adrenergic stimuli, drugs, or more sustained physiologic factors, such as pregnancy, hypothyroidism, chronic illness, or long-term use of certain medications. The vasopressin analog, 1-deamino-(8-D-arginine)-vasopressin (DDAVP, desmopressin) transiently and reliably increases vWF and FVIII levels—a fact that, in addition to an acceptable side effect profile, has led to the use of desmopressin as first-line treatment in certain types of vWD and mild hemophilia A. Several physiologic stressors involving β-adrenergic stimulation, such as exercise[19,20] and psychologic distress, can produce an acute increase in vWF levels. Similarly, surgery and trauma are also associated with an immediate increase in vWF levels. vWF levels remain elevated for up to 6 days after surgery,[21] suggesting that after the acute secretory response, there is upregulation of vWF production. A sustained elevation of vWF levels can occur with chronic diseases, such as hyperthyroidism, renal failure, diabetes, liver disease, atherosclerosis, chronic inflammatory states, and cancer.[10] Conversely, acquired vWD, characterized by qualitative or quantitative vWF defects, can occur with certain medications, such as valproic acid, and with some chronic medical conditions (see section later on acquired vWD).

vWF levels are increased by estrogen. In premenopausal women, vWF levels vary in a cyclical fashion, with the lowest levels occurring in the early follicular phase of the menstrual cycle (days 1 to 7) and peak values occurring during the luteal phase.[17] Oral contraceptives increase vWF levels and dampen the cyclical variation. This dose-dependent effect is mediated by the estrogen component and evident with ethynylestradiol doses of 0.5 mcg or higher. Lower estrogen doses have little or no effect on vWF levels. vWF levels increase in pregnancy starting in the second trimester and achieve levels threefold higher than baseline values by the end of the third trimester.[11,22] vWF levels return to baseline 2 to 3 weeks after delivery.

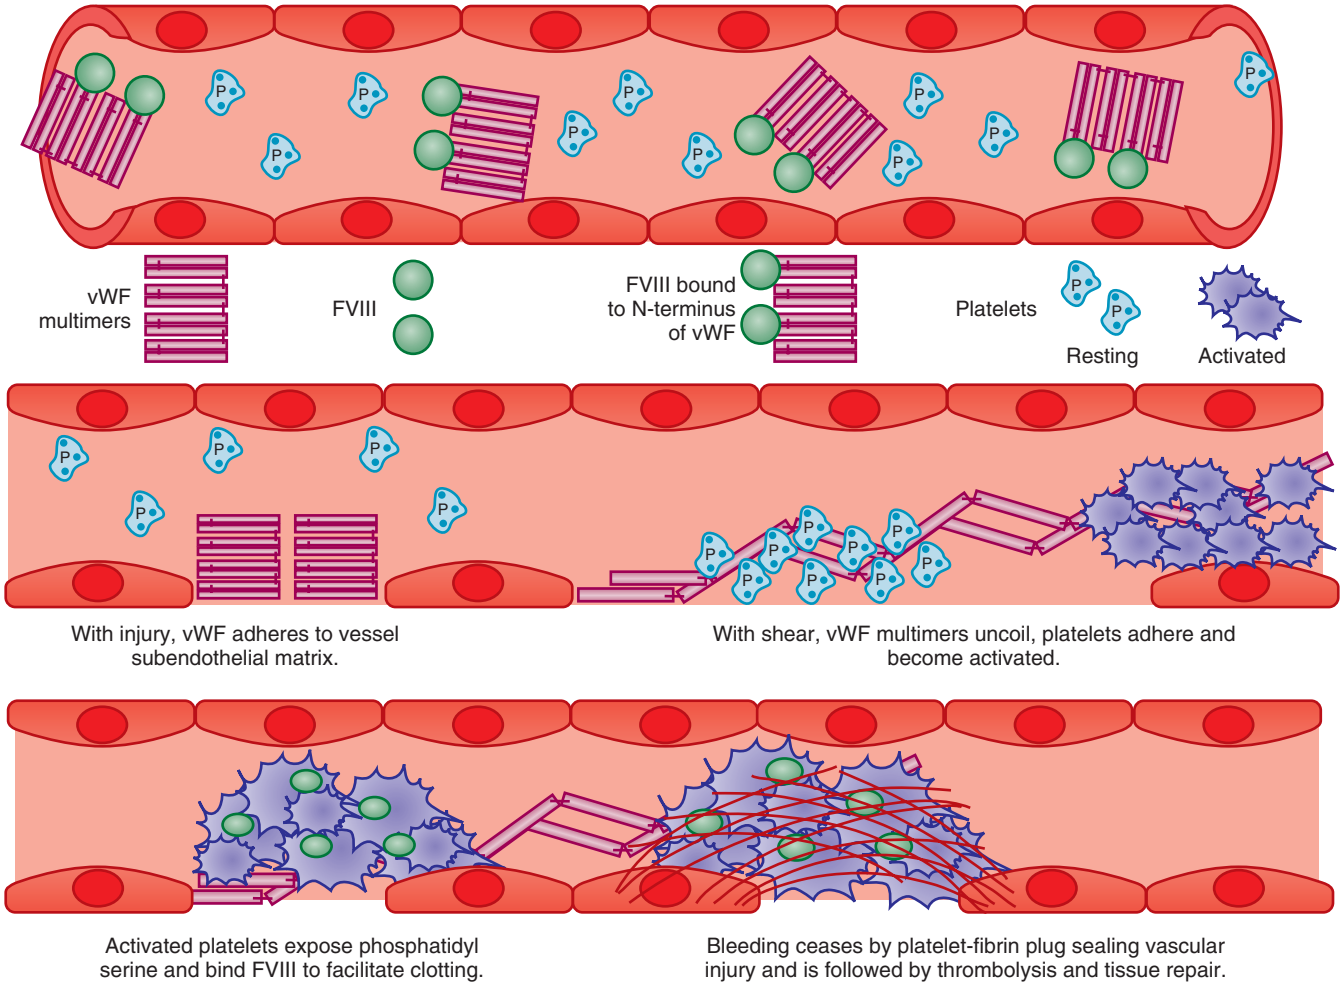

Figure 140-1 FUNCTION OF vWF. Role of vWF in mediating the initial events in the hemostatic process. vWF is the carrier protein for FVIII *(top).* After endothelial injury, vWF adheres to the exposed subendothelium, where it is uncoiled by the shear forces, thereby exposing GP1bα binding sites that interact with platelets *(middle).* The bound platelets are activated, and the GpIIb-IIIa complex is exposed on the platelet surface. Interaction of fibrinogen and vWF with GpIIb-IIIa then consolidates the platelet adhesive event and initiates platelet aggregation *(bottom). (Used with permission of Robert Montgomery.)*

vWF GENE

The vWF gene was cloned and characterized by four groups simultaneously in 1985.[3-6] Located on the short arm of chromosome 12 at p13.3, the vWF gene spans 178 kb and is composed of 52 exons that range in size from 1.3 kb (exon 28) to 40 bp (exon 50)[23] (Fig. 140-2). In humans, there is a partial, unprocessed pseudogene, vWFP, located on the long arm chromosome 22 at q 11.2, measuring 21 to 29 kb, which duplicates the vWF gene sequence for exons 23-34 with 97% sequence homology. The pseudogene contributes to the mutation spectrum of vWD through gene conversion,[24] although the frequency of this is unknown. The vWF gene is highly polymorphic. To date, more than 160 polymorphisms have been identified in the exons and closely flanking intronic sequences; these normal variants include promoter polymorphisms, a highly variable tetranucleotide repeat in intron 40, two insertion/deletion polymorphisms and 132 distinct single-nucleotide polymorphisms (SNPs) involving exon and intron sequences. An ISTH-SSC (International Society on Thrombosis and Haemostasis Scientific and Standardization Committee) database of both polymorphisms and mutations is maintained at the University of Sheffield (http://www.shef.ac.uk/vwf/). The high degree of polymorphism in the vWF gene, the large size of the gene, and the presence of the pseudogene render full gene sequencing and data interpretation challenging.

The vWF amino acid sequence contains four homologous repeated segments, named A through D, which make up approximately 90% of the precursor. These homologues also occur in a number of unrelated proteins. For example, vWF A domains appear in up to 22 human genes, such as leukocyte adhesion receptors, collagen receptors, and cartilage matrix protein. Likewise, homologues of vWF domains B, C, D, and CK exist throughout the genome, where they are found in proteins with various functions. This suggests that the vWF gene is the product of a complex series of partial gene duplications.[23]

The expression of the vWF gene is tightly restricted to endothelial cells, platelets, and megakaryocytes. Cell-specific transcriptional regulation is complex and poorly understood. A 734–base pair region, spanning approximately 500 bases of the 5′-flanking region and 247 bases into the first exon, functions as a promoter and includes a minimal core promoter, as well as negative and positive regulatory regions.[25] The positive regulatory region confers cell-specificity by relieving inhibition in specific cells, thereby allowing transcription of the vWF gene.

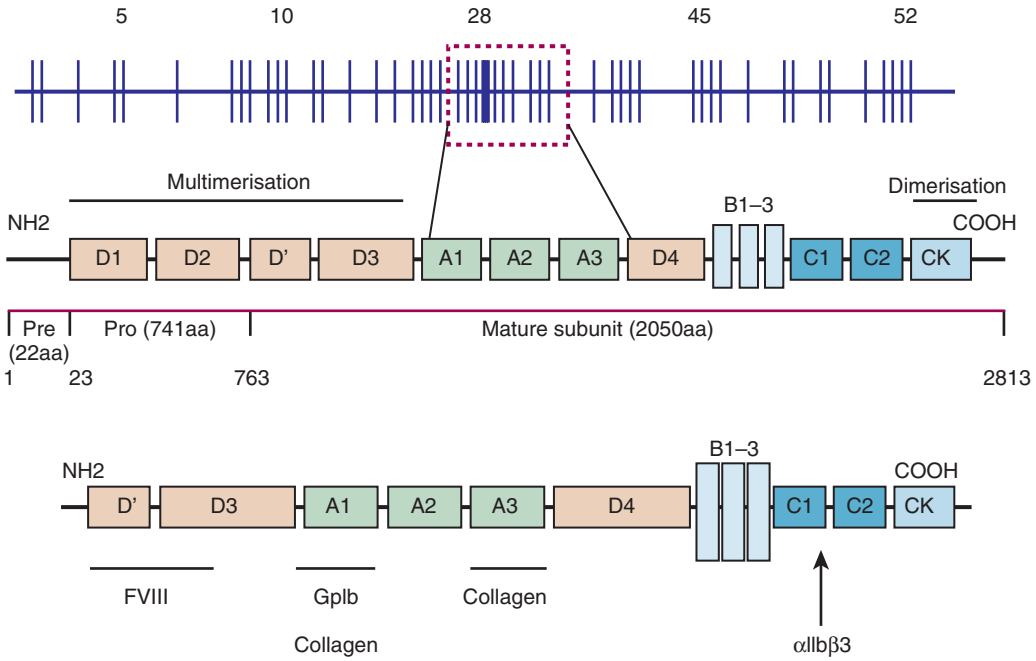

Figure 140-2 vWF GENE, mRNA AND PROTEIN. The vWF *gene* is located on chromosome 12 at p13.3 and spans 178 kb and includes 52 exons. The mRNA is 8.8 kb in length. Prepro-vWF contains 2813 amino acids (AA) with a 22-AA signal peptide, a 741-AA propeptide, and a 2050-AA mature subunit. The mature subunit consists of repeated domains *(A-D),* several of which have distinct functions and binding sites.

DOMAIN STRUCTURE

Encoded vWF mRNA is 8.8 kb in length and the translated prepro-vWF molecule contains 2813 amino acids (AA), comprising a 22 AA signal peptide, a 741 AA propeptide, and a 2050 AA secreted mature subunit that possesses all of the adhesive sites required for the hemostatic function of vWF.[26,27] The AA sequence is rich in cysteine residues, which make up 8.3% of the prepro-vWF and are abundant in all of the domains except the A domains, where only six cysteine residues are found. Cysteine residues are involved not only in interchain disulfide bonds, but also in intrachain disulfide bonds.

The domain structure of vWF, which consists of repeated domains, is arranged in the following sequence: S-D1-D2-D′-D3-A1-A2-A3-D4-B1-B2-B3-C1-C2-CK. Functional domains important for multimerization, cleavage, and binding have been identified. The signal peptide (S) targets prepro-vWF to the endoplasmic reticulum (ER), where it is promptly cleaved. The cysteine knot (CK) domains of adjacent vWF monomers form disulfide bonds, resulting in tail-to-tail dimers. The vWF pro-peptide (domains D1-D2), previously known as vWF antigen II, plays an important role in vWF multimer assembly by promoting the formation of head-to-head oligomers through disulfide bonds involving D3.[28] The A2 domain contains the Tyr1605-Met1606 cleavage site for ADAMTS13 (a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13), which reduces both the size and the thrombogenicity of vWF multimers within the circulation.

Integral to vWF function, the vWF subunit possesses several binding sites, almost entirely encoded by exon 28 and including domains D′-D3-A1-A2-A3. In addition, the C1 domain, encoded by exons 42-44, contains a binding site. The D′ and D3 domains contain the FVIII-binding sites,[29] which interact with the N-terminus portion of the FVIII light chain.[30] vWF interacts with platelets via two platelet receptors; glycoprotein Ibα (GPIbα) and GPIIb/IIIa, which mediate platelet adhesion to injured subendothelium and the aggregation of activated platelets, respectively. The binding site for GPIbα is localized within the large disulfide loop of A1,[31] whereas the binding site for GPIIb/IIIa is found within the RGD sequence of C1.[9] The major binding site for collagen is found within the A3 domain, but the A1 domain has also been shown to bind collagen.[32,33]

BIOSYNTHESIS

von Willebrand factor is synthesized in endothelial cells[34] and megakaryocytes[35] as a protein subunit that undergoes a complex series of posttranslational modifications, including dimerization, glycosylation, sulfation, and ultimately, multimerization. The fully processed protein is then either released into the circulation or is stored in specialized organelles: the Weibel-Palade bodies (WPBs) of endothelial cells or the α-granules of platelets.

Dimerization of pro-vWF monomers occurs in the endoplasmic reticulum through the formation of disulfide bonds between CK domains monomers in a "tail-to-tail" fashion. The location of these intersubunit disulfide bonds has been localized to a subset of cysteine residues (Cys2771, Cys2773, and/or Cys2811).[36] In addition, the signal peptide is cleaved and most of the intrachain disulphide bonds are formed in the ER. Only pro-vWF dimers are then transported to the Golgi apparatus, where they make up the basic building blocks for further multimerization. Here, the propeptide (D1-D2) is cleaved by a propeptide processing protease, likely furin, between amino acids 763-764. The propeptide continues to be essential for vWF multimerization because under acidic conditions, it serves as an endogenous chaperone that promotes additional disulfide bond formation between D3 domains of adjacent dimers in a "head-to-head" orientation.[37] The intersubunit disulfide bonds are likely mediated by the alignment of the cysteine pairs C1099 and C1142.[38] The vWF subunit is approximately 250 kDa, whereas resulting disulfide-linked multimers can be more than 20,000 kDa (Fig. 140-3).

The mature vWF subunit is heavily glycosylated with carbohydrate making up approximately 20% of the mass of the mature subunit.[26] Although the function of these oligosaccharide chains is largely unknown, they appear to protect vWF from proteolytic degradation,[39] maintain the multimeric structure of vWF,[40] affect vWF

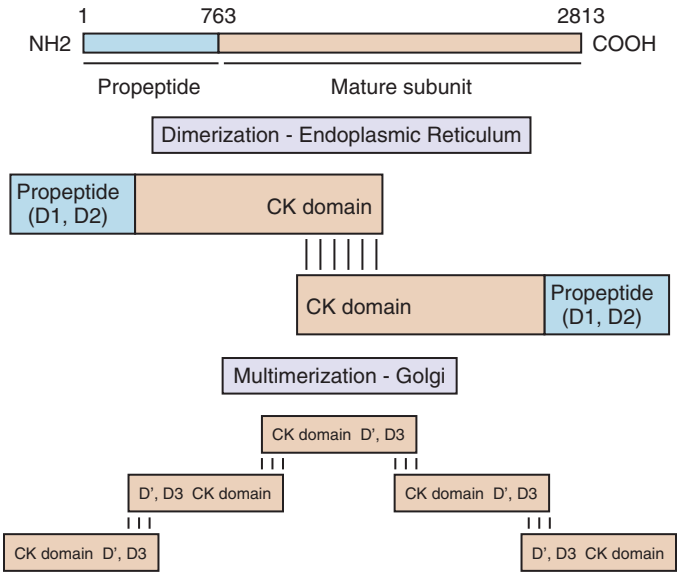

Figure 140-3 MULTIMERIZATION OF vWF SUBUNITS. Dimerization of pro-vWF monomers occurs in the endoplasmic reticulum (ER) through disulfide linkage of CK domains in a "tail-to-tail" fashion. Only pro-vWF dimers are transported to the Golgi, where they constitute the building blocks for further multimerization. Although the propeptide (D1-D2) is cleaved by a propeptide processing protease, it is essential for vWF multimerization because it serves as a chaperone that promotes further disulfide bond formation between adjacent D3 domains in a "head-to-head" orientation.

interaction with platelets and collagen, and influence plasma clearance of vWF.[41] In the ER, 12 N-linked high-mannose-containing oligosaccharide chains are added to each vWF subunit, and these appear to be necessary for vWF subunit dimerization. In addition, the propeptide has three additional potential N-glycosylation sites. Posttranslational modification continues in the Golgi with the addition of 10 O-linked oligosaccharides to the peptide chain, and the sulfation of certain N-linked oligosaccharides, such as Asn384 and Asn468.[27] The previously added N-linked glycans undergo further processing with the addition of ABO groups, as determined by the ABO genotype, in the post-Golgi compartment.[42] ABO blood groups affect the proteolysis of vWF by ADAMTS13[43] as well as the clearance of vWF from the circulation[41] (see the later section on ABO blood groups). The cleaved propeptide remains noncovalently associated with vWF multimers and is stored and secreted with the mature vWF in a 1:1 molar ratio.

STORAGE AND SECRETION

Most of the vWF in endothelial cells consists of small multimers that are constitutively secreted. The more biologically active high-molecular-weight (HMW) vWF multimers are preferentially targeted for storage in endothelium-specific cytoplasmic granules called *Weibel-Palade bodies.*[44] In addition to vWF and the vWF propeptide, WBPs also store P-selectin, CD63, IL-8,[45] tissue plasminogen activator (tPA),[46] and angiopoietin-2.[47] Thus WPBs store proteins that are involved not only in hemostasis, but also in inflammation, hemodynamics, and angiogenesis. WPBs have a characteristic cigar-like shape, measuring 0.2 μm wide and 5 μm long (Fig. 140-4), and are composed of tightly packed tubules, measuring 150 Å to 200 Å in cross-section. Platelet vWF is stored within similar tubules that are found in the periphery of α-granules[48] and constitutes approximately 15% of total blood vWF. Tubular packing condenses the length of vWF multimer by 50-fold[49] and is dependent on the acidic pH within the trans Golgi, as well as the propeptide (D1D2) and the NH_2-terminal region (D′D3A1).[50] Long vWF multimers, which can be up

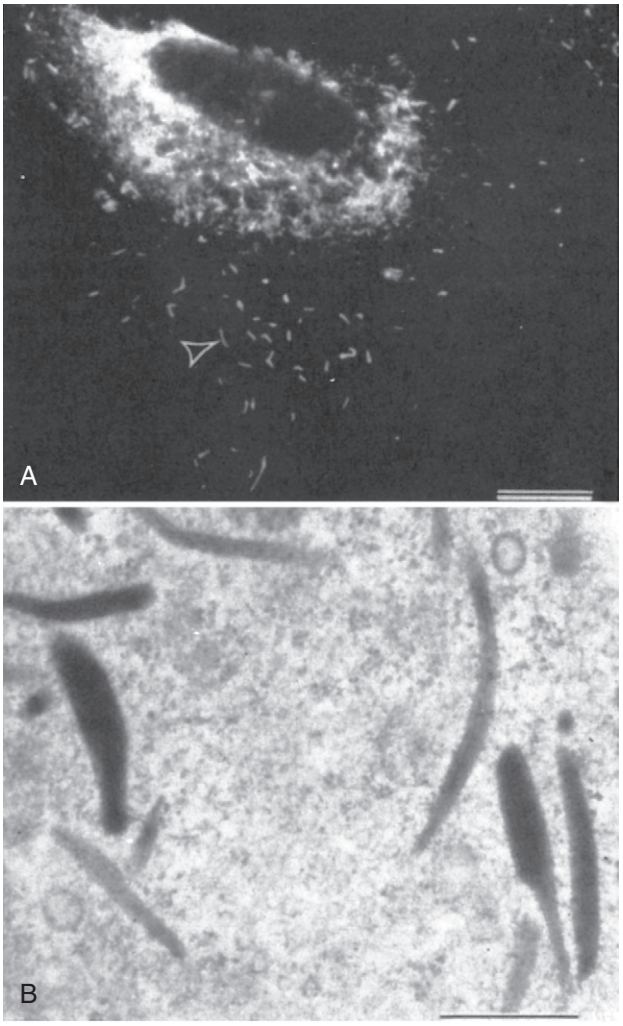

Figure 140-4 WEIBEL-PALADE BODIES OF ENDOTHELIAL CELLS. **A,** Immunofluorescence staining of a human umbilical vein endothelial cell with anti-vWF antiserum. vWF is present in the perinuclear region, where it is synthesized, and in the Weibel-Palade bodies *(arrowhead)* throughout the cytoplasm. Bar = 10 μm. **B,** Electron micrograph of Weibel-Palade bodies of the same origin. Bar = 0.5 μm. *vWF,* von Willebrand factor.

to 100 μm, are reversibly packaged into coils. With WPB exocytosis, the filamentous strings of vWF are secreted into the circulation, where they rapidly unfurl and are capable of binding to platelets. If the tubular structure is perturbed, WPBs release short, tangled vWF that does not support platelet binding to the endothelium.

A variety of agonists can induce the secretion of vWF from endothelial cells. These agonists include histamine, thrombin, fibrin, the terminal complement proteins C5b-9, and β-adrenergic agonists. With endothelial cell stimulation, WPBs fuse with the plasma membrane to form a secretion pore. This leads to a rapid rise in pH and release of intracellular calcium stores.[51] The freshly secreted unusually large (or ultra-large) vWF multimers (ULvWF) are highly active and can spontaneously bind platelets. Some of the released protein remains associated with the endothelial membrane,[52] and some self-associate.[53] The activity of these ULvWF multimers is regulated by ADAMTS13-mediated proteolysis.

ADAMTS13

ADAMTS13 is a plasma protease that cleaves circulating vWF between Tyr 1605 and Met 1606 in the A2 domain. ADAMTS13 regulates the function of vWF. Its main target is the ULvWF

multimers, which spontaneously bind GPIbα platelet receptor; it cleaves these multimers when they under sufficient shear to unfold the A2 domain the cleavage site is exposed.[54] ULvWF multimers that appear in plasma after WPB secretion are cleaved within 2 hours by ADAMTS13 to form shorter, less hemostatically active multimers.[55] Proteolysis of vWF multimers is responsible for the characteristic "triplet" pattern of satellite bands flanking each main multimer band that is observed on multimer analysis gels.

vWF proteolysis is influenced by glycosylation and specific polymorphisms. For example, nonglycosylated recombinant vWF is degraded more rapidly than its plasma-derived glycosylated counterparts.[39] Likewise, addition of A or B blood group antigens to N-linked oligosaccharide chains of vWF reduces ADAMTS13 proteolysis compared with vWF bearing the O blood group antigen.[43] Single-nucleotide polymorphisms, such as the A/G polymorphism at position 24/1282 resulting in Tyr/Cys at 1584, have also been shown to affect the susceptibility of vWF to proteolysis.[56]

Alterations in the balance between ADAMTS13 activity and vWF proteolysis can lead to a number of disease states. Congenital or acquired deficiency of ADAMTS13 can result in thrombotic thrombocytopenic purpura (see Chapter 136). On the other hand, enhanced proteolysis can give rise to a bleeding phenotype. For example, mutant vWF in a subtype of type 2A vWD exhibits enhanced susceptibility to ADAMTS13 cleavage, which results in loss of large vWF multimers[57] (see the later section on vWD type 2A).

CLEARANCE

Although the mechanism and location of vWF clearance is largely unknown, data suggest that macrophages in the liver and spleen internalize and clear vWF in a process that is independent of multimer size.[58] In a recent metaanalysis of genome-wide association studies, loci outside of the vWF gene that contribute to the highly variable vWF levels in normal populations were identified.[59] CLEC4M (C-type lectin domain family 4, member M) and STAB2 (stabilin 2) are two transmembrane sinusoidal endothelial cell receptors that may be involved in vWF clearance. Further studies are needed to explore this possibility.

The cleaved propeptide remains associated with vWF multimers stored in WPB and is secreted in a 1:1 molar ratio with the mature vWF subunit. After secretion, the propeptide (vWFpp) dissociates from vWF and circulates at a concentration of approximately 1 mcg/mL. The propeptide has a half-life of 2 to 3 hours and no known function.[60] In contrast, vWF circulates at a plasma concentration of approximately 10 mcg/mL and has a half-life of approximately 8 to 12 hours. The ratio between vWFpp and mature vWF (vWFpp/vWF:Ag) can be used to estimate the relative half-life of mature vWF; elevated ratios indicate enhanced clearance.[61]

Changes in vWF glycosylation or point mutations can be associated with increased clearance. Blood group O subjects (see the following section on ABO Blood Groups) exhibit increased vWF clearance compared with the other blood types and have consistently elevated vWFpp/vWF:Ag ratios and shorter vWF survival after desmopresssin.[41]

Several point mutations may lead to increased vWF clearance and are associated with either a type 1 or type 2A vWD phenotype.[62] The vast majority of these are localized to the D3 domain (e.g., R1205H and C1130F), but point mutations in the A1 (I1416N), CK (C2617), and D4 domains (S2179F) have also been implicated.

vWF mutations associated with increased clearance are not necessarily associated with increased susceptibility to proteolysis by ADAMTS13 and vice versa.[63,64] For example, the vWD Vicenza mutation, R1205, is the prototypical clearance mutation. Patients with this mutation have severely reduced plasma FVIII and vWF levels, an increased vWFpp/vWF:Ag, and a marked increase in FVIII and vWF after desmopressin with a significantly shortened half-life of 1 to 2 hours. However, there is no association between increased clearance of this mutant vWF and altered susceptibility to ADAMTS13 proteolysis.[65]

ABO BLOOD GROUPS

Blood group O subjects have vWF levels that are on average 25% lower than those with non-O blood type: the mean vWF level in blood group O subjects is 74.8 IU/dL as compared with 105.9 IU/dL, 116.9 IU/dL and 123.3 IU/dL in blood group A, B and AB subjects, respectively.[15] ABO antigens are added to N-linked oligosaccharide chains on the vWF subunit. Thus patients with the type O blood group genotype lack a functional glycosyltransferase that adds *N*-acetylgalactosamine and *D*-galactose to the H antigen on vWF in blood group A and B subjects, respectively. Altered glycosylation of vWF in subjects with blood type O leads to lower plasma vWF levels as a result of increased proteolysis and/or increased clearance. Blood group O vWF is more susceptible to ADAMTS13 proteolysis,[43] and blood group O subjects have elevated vWFpp:vWFAg ratios and shorter vWF survival after desmopressin.[41] The mean half-life of vWF in type O subjects is approximately 10 hours compared with a half-life of approximately 25.5 hours in those with other ABO blood types. Clinically, the difference in vWF levels results in an overrepresentation of blood group O patients with type 1 vWD, which is defined by a reduction in vWF levels.

AREAS OF ONGOING INVESTIGATION

There is emerging evidence that vWF may have a role in the regulation of VEGF-dependent angiogenesis directly through its interaction with integrins on endothelial cells and indirectly via regulation of WPB formation and secretion of constituents such as angiopoietin-2.[66] In addition, vWF may protect against tumor metastasis.[67,68] Patients with increased vWF levels are at risk for cardiovascular events; it is unclear whether vWF contributes to atherosclerosis or whether it is a marker of endothelial dysfunction.[69] Nonetheless, vWF plays an important role in atherothrombosis, and drugs targeting vWF attenuate arterial thrombosis in animal models. Their utility in humans is unknown.

VON WILLEBRAND DISEASE

vWD, which is caused by deficient or defective plasma vWF, is the most common inherited bleeding disorder, affecting as much as 0.1 to 1% of the population.[70-72] The most common bleeding symptoms reflect the defect in primary hemostasis: mucocutaneous bleeding, especially epistaxis and menorrhagia. In some cases, FVIII levels may be sufficiently low that the bleeding phenotype overlaps with that of mild to moderate hemophilia; these patients may experience joint or muscle bleeds. The current vWD classification recognizes three subtypes.[73] Type 1 vWD is characterized by quantitative deficiency of essentially normal vWF, type 2 vWD is characterized by qualitative defects in vWF, and type 3 vWD is characterized by an almost complete quantitative deficiency of vWF. The classification incorporates important aspects of clinical phenotype, pathophysiologic mechanisms, and treatment considerations. The two main treatments are desmopressin (1-deamino-8-D-arginine vasopressin [DDAVP]) and clotting factor concentrates containing both vWF and FVIII (vWF/FVIII concentrate). Other treatment options include antifibrinolytic agents (tranexamic acid) and hormone therapy (oral contraceptive pill). Areas of ongoing research include defining the role of prophylaxis in vWD, optimizing the use of current therapies, such as tranexamic acid, and development of recombinant vWF replacement products.

Epidemiology

vWD is the most common inherited bleeding disorder. However, because vWF levels are highly variable in the populations and disease severity ranges from infrequent, mild bleeding symptoms to frequent, severe, or life-threatening bleeds, the prevalence of vWD depends on

the diagnostic criteria and the study population. In two large epidemiologic studies, the prevalence of vWD was approximately 1% in healthy school-age children based on low vWF activity, measured as ristocetin cofactor, and a personal and family history of bleeding symptoms.[70,71] More recent studies suggest that the prevalence of vWD in individuals who present to a primary care physician with bleeding symptoms is approximately 0.1%,[74] whereas in patients whose bleeding symptoms are sufficiently severe to warrant referral to specialized centers, the prevalence of vWD ranges from 20 to 113 per million.[10]

Classification and Pathophysiology

The ISTH classification of vWD was updated in 2006.[73] This classification is clinically useful and relies on the vWF protein phenotype, which in turn often reflects the underlying pathophysiology and has implications on treatment approach. There are three primary categories: type 1, which is a partial quantitative deficiency; type 2 (with four subtypes—2A, 2B, 2M, and 2B), which is a qualitative defect; and type 3, which is a virtual deficiency of vWF (Table 140-1). In most cases, the diagnosis and categorization of vWD into a type can be achieved with widely available laboratory testing. However, further subcategorization, such as the differentiation among certain vWD type 2 subtypes, may require referral to a specialized laboratory. Because gene sequencing is not widely available, the current classification does not incorporate genotypic data. Also, the diagnosis of vWD is not limited to individuals with mutations within the vWF gene; vWF mutations may not be identified in vWD patients because of the complexity of the vWF gene, and mutations in other genes, such as those affecting secretion or clearance, also lead to a vWD phenotype. A third level of classification denoted by Roman numerals (e.g., vWD type 2A IIA) indicates specific phenotypes and is a remnant of an older classification system that is mainly used in the research setting (Table 140-2).

vWD Type 1

Type 1 vWD, a partial quantitative deficiency of vWF, represents approximately 70% of vWD cases. The vWF is functionally normal without a specific abnormality in ligand binding sites or a significant decrease in HMW multimers. Functional assays of vWF, such as vWF:RCo, are decreased in proportion to the decrease in vWF:Ag concentration, and the ratio of functional activity as compared with vWF:Ag is normal (i.e., vWF:RCo/vWF:Ag ratio is >0.6). Thus bleeding in this disorder is the result of decreases in the concentration of normal vWF.

Table 140-1 Classification of von Willebrand Disease

Type	Description
1	Partial quantitative deficiency of vWF. Mild abnormalities in multimer structure or distribution may occur.
2	Qualitative vWF defects.
2A	Decreased vWF-dependent platelet adhesion and deficiency of HMW vWF multimers.
2B	Increased affinity for platelet GPIbα.
2M	Decreased vWF-dependent platelet adhesion with a normal multimer distribution.
2N	Decreased affinity for FVIII.
3	Almost complete deficiency of vWF.

FVIII, Factor FVIII; *HMW*, high-molecular-weight; *vWF*, von Willebrand factor.

Point mutations, most frequently missense mutations, have been identified in approximately 65% of individuals with type 1 vWD and occur throughout the vWF gene.[75-77] Fully penetrant, dominantly inherited missense mutations are more often identified when vWF:Ag and vWF:RCo levels are less than 25 IU/dL. In contrast, incompletely penetrant, dominantly inherited missense mutations, such as p.Tyr1584Cys and p.Arg924Gln are identified in approximately 50% of individuals whose vWF:Ag and vWF:RCo levels are above 25 IU/dL.[77,78] The extent to which incompletely penetrant vWF mutations contribute to bleeding phenotype in individuals with vWF levels of about 50 IU/dL is not clear, and genetic analyses in such cases are difficult to interpret.

Missense mutations may affect vWF levels by reducing secretion and/or increasing clearance. The most frequently reported genetic mutation is a missense mutation that results in the substitution of tyrosine with cysteine at codon 1584 (Y1584C), which is found in 10% to 20% of type 1 vWD patients.[75-77] Intracellular retention is a common mechanism for type 1 vWD pathogenicity and can result from missense mutations in various vWF domains.[79] Haploinsufficiency from a heterozygous null allele results in reduced vWF expression in a small proportion of cases. A common heterozygous in-frame large deletion of exons 4-5 was reported in a cohort of type 1 vWD patients[80] in the United Kingdom, and this and similar partial gene deletions may contribute to the spectrum of mutation in a minority of cases. A well-described pathophysiologic mechanism for vWD type 1 is increased vWF clearance.[62] Patients with increased clearance typically have very low vWF levels, an increased vWFpp/vWF:Ag ratio, and a marked but short-lived response to desmopressin. Of note, the half-life of vWF/FVIII concentrates is normal in these individuals.[81] Missense mutations mainly occur in the D3 domain and reduce the half-life of vWF up to 15-fold. R1205H, which is known as the "Vicenza" variant, is the most common, most severe, and best characterized of these mutations.[82,83] Such mutations have been referred to as *type 1C* (C for increased clearance), although this designation is not included in the ISTH classification. Because of the transient response to desmopressin, the utility of this medication for treatment of major bleeds is questioned in this subgroup of patients. However, desmopressin may still be useful for management of most minor bleeds or minor surgical procedures.[84]

vWD Type 2

Type 2 vWD is characterized by a qualitative deficiency of vWF activity and is further classified into the qualitative variants that affect

Table 140-2 Subclassification of Type 2 vWD

Subtype	Location of Missense Mutations (Domains)	Inheritance	Mechanism
IIA	A1, A2	Dominant	Enhance susceptibility to ADAMTS13 proteolysis
IIC	D1, D2	Recessive	Affects the propeptide and results in impaired multimer assembly
IID	CK	Dominant	Impaired dimer assembly
IIE	D2, D3	Dominant	Usually involves a cysteine residue important for intersubunit disulfide bonds and multimerization

vWF-platelet interactions (2A, 2B, and 2M) and the rare type 2N characterized by defective vWF binding to FVIII. Type 2 vWD is often suspected when investigations demonstrate a function discordance: the vWF:RCo, a function of platelet GP1B binding, is decreased out of proportion to the decrease in vWF:Ag, and a vWF:RCo/vWF:Ag ratio of less than 0.6 occurs (Fig. 140-5).

Type 2A

vWD type 2A is the most common type 2 variant, accounting for approximately 10% of all vWD cases. vWD type 2A usually is inherited as a dominant trait (although some variants are recessive) and is characterized by disproportionately low functional activity compared with antigen level (i.e., vWF:RCo to vWF:Ag ratio of <0.6). The FVIII level may be low or normal. Ristocetin-induced platelet agglutination (RIPA) is reduced, and the multimer profile shows a loss of HMW and sometimes intermediate-molecular-weight (IMW) multimers. This subtype may encompass missense mutations that impair dimer (CK domain)[85] or multimer assembly (recessive mutations in the D1 and D2 domains),[86,87] disrupt intersubunit disulphide bonds (D3 and D2 domains), enhance susceptibility to ADAMTS13-mediated proteolysis (A2 and A1 domains),[88] and/or result in intracellular retention of vWF, particularly the HMW multimers (D3, A1, and A2 domains).[89] High-resolution multimer gel electrophoresis patterns can provide clues as to the specific disease mechanism and recognize the following categories: IIA, IIC, IID, and IIE (see Table 140-2). All patterns result in the synthesis of vWF that possesses fewer GpIbα binding sites and is less effective in platelet clot formation. Regardless of the mechanism, clinically affected individuals are treated similarly.

Type 2B

Type 2B vWD is the result of gain-of-function mutations within the GpIbα binding site on vWF. Missense mutations are located in exon 28, in or close to the A1 domain.[90] This results in spontaneous binding of vWF to platelets without the need for a vWF collagen interaction. The vWF-platelet interactions selectively depletes the HMW multimers by increasing ADAMTS13 proteolysis.[90,91] The increased binding of mutant vWF to platelets also triggers the formation of platelet aggregates, which are removed from the circulation resulting in thrombocytopenia. Altered megakaryocytopoiesis characterized by giant platelets with abnormal ultrastructure contributes to the thrombocytopenia.[92]

The laboratory profile reveals a decreased vWF:RCo to vWF:Ag ratio and absence of HMW multimers, but in contrast to 2A, RIPA reveals increased sensitivity to low doses of ristocetin. Although these features may be present to varying degrees in the majority of patients, not all cases demonstrate these classic features. For example, mutations affecting p.Pro1266Leu may enhance GpIbα binding (RIPA) without inducing thrombocytopenia or HMW multimer loss.[93]

Type 2M

Type 2M vWD (the *M* refers to *multimer*) is characterized by decreased vWF-platelet interactions. The laboratory workup shows a reduced ratio of vWF:RCo to vWF:Ag but a normal multimer pattern. RIPA is also reduced. A number of missense mutations are reported in exon 28, with case reports in exons 27, 30-31, and 52. vWF exhibits reduced affinity for GpIbα, because of mutations in the A1 domain that alter protein conformation, but HMW multimers are normal.[94] Mutations in the A3 domain that impair the vWF/collagen interaction[95,96] are also classified as 2M vWD. In these cases, vWF:RCo may be normal, and the diagnosis requires vWF/collagen binding assays (vWF:CB).

Type 2N

Type 2N vWD (with the *N* referring to *Normandy,* where the first cases were reported) has been described as an autosomal form of hemophilia A and is important in the differential diagnosis of individuals of either sex who present with low FVIII levels. The characteristic laboratory feature is a disproportionate reduction in the FVIII level relative to the vWF level (which may be low or normal) with a resultant FVIII/vWF:Ag ratio that is reduced.[97] Affinity of vWF for FVIII is reduced because of mutations of the FVIII binding site or conformational changes that impair the vWF-FVIII interaction. The majority of patients with vWD type 2N have a normal multimeric profile, but occasional cases will demonstrate loss of HMW multimers. The majority (≈ 80%) of missense mutations are located in exons 18-20 (D′ and D3) with a much lower proportion of mutations in exons 17 and 24-27.[98] Type 2N exhibits autosomal recessive inheritance, and affected individuals are either homozygous or compound heterozygous for missense mutations, or compound heterozygous for a missense mutation and a mutation resulting in a null allele. The latter mutations are found throughout the vWF gene; p.Arg854Gln occurs in 2% of white populations and frequently contributes to the phenotype.[99,100] Definitive diagnosis requires evidence of reduced FVIII binding to vWF (vWF:FVIIIB) or the identification of causative mutations in the FVIII binding region of the *vWF* gene.[101]

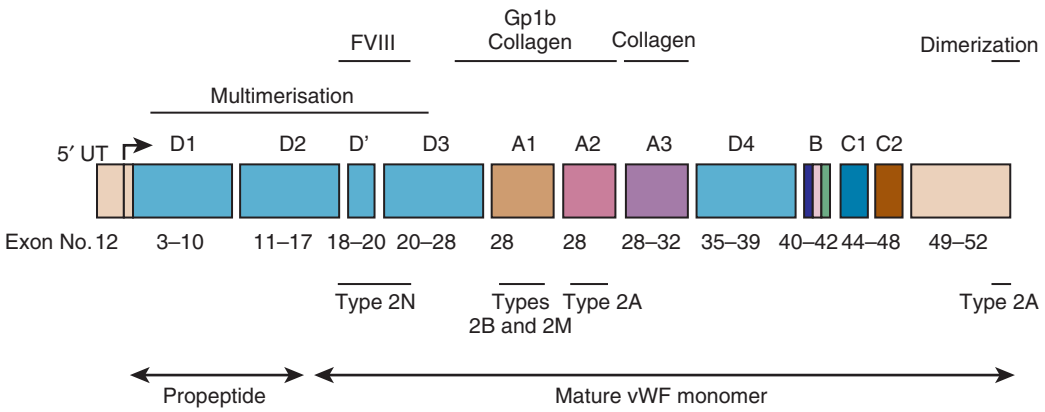

Figure 140-5 FUNCTIONAL DOMAINS OF vWF AND LOCATION OF TYPE 2 vWD MUTATIONS. vWF protein comprises a large N-terminal propeptide and mature subunit. Repeated protein domains are designated *A* through *D.* Highlighted are binding sites for factor VIII, platelet Gp1b, and collagen and the areas critical for dimerization and multimerization. Sites of the common mutations that result in type 2 vWD are shown. *Arrow* indicates translational start site.

Type 3 vWD

This subtype of vWD is defined by a virtual absence of vWF. The inheritance of type 3 vWD is autosomal recessive, and although parents of affected individuals are often asymptomatic, there is growing evidence that obligate carriers of type 3 vWD mutations have more mucocutaneous bleeding symptoms than normal individuals.[102] This condition is characterized by prolongation of the aPTT, undetectable levels of vWF:Ag, and vWF:RCo and FVIII levels less than 10 international units/dL (10%). Mutations associated with type 3 vWD are found throughout the coding region of vWF (i.e., exons 2-52). Up to 80% of type 3 vWD patients have two null alleles and produce little or no vWF. Null alleles can result from a variety of mutations, with nonsense mutations accounting for about one-third of these.[103] Approximately 20% of alleles carry missense mutations predominantly located in the D1-D2 (exons 3-11) and D4-CK (exons 37-52) domains. These mutations may impair dimer or multimer formation, resulting in intracellular vWF retention and decreased secretion into plasma.[104] Large deletions, predominantly resulting in frameshift mutations affecting one or more exons, contribute to approximately 12% of the type 3 vWD mutation spectrum. Because there is little or no circulating vWF, patients with these mutations may develop alloantibodies to infused vWF, which can complicate treatment.[105]

Clinical Manifestations

Although vWD is a congenital bleeding disorder, symptoms may manifest only when there is a hemostatic challenge. Consequently, bleeding symptoms become more obvious with increasing age. The bleeding history also depends on disease severity; type 3 vWD is often diagnosed early in life, whereas mild type 1 vWD may not be diagnosed until adulthood, despite a history of bleeding episodes. Individuals with vWD primarily complain of excessive mucocutaneous bleeding, such as bruising without recognized trauma, prolonged, recurrent nose bleeds, and oral cavity bleeding, including bleeding from the gums after brushing or flossing the teeth or prolonged bleeding after dental cleaning or extractions. In addition, prolonged or excessive bleeding after surgery or trauma is often reported. Affected females frequently experience menorrhagia, usually since menarche, and have prolonged or excessive bleeding after childbirth.[106,107] Musculoskeletal bleeding is unusual, except in type 2N or type 3 vWD when the FVIII:C level may be below 10 international units/dL. Clinical assessment scoring tools are helpful for vWD diagnosis (see Chapter 130) (see box on Case Example of the Presentation and Impact of Type 1 vWD).

Type 1 vWD accounts for up to 70% of vWD. It typically manifests as mild mucocutaneous bleeding; however, symptoms may be more severe if vWF levels are below 15 international units/dL. Epistaxis and bruising are common symptoms in children. Menorrhagia is the most common finding in women of reproductive age.

Type 2 vWD accounts for about 25% of all vWD. The relative frequency of the subtypes is 2A>2N>2M>2B in European populations. Individuals with type 2A, 2B, and 2M vWD usually present with mild to moderate mucocutaneous bleeding, but bleeding episodes can be severe, particularly when vWF:RCo is very low or absent. In many patients with type 2B vWD, thrombocytopenia can develop or worsen with infection, surgery, pregnancy, or treatment with desmopressin.[93] The symptoms of type 2N vWD are similar to those seen in mild hemophilia A (see Chapter 137) because both disorders are associated with reduced levels of FVIII:C.

Type 3 vWD is the most rare of the subtypes and accounts for less than 5% of vWD. Prevalence estimates range from 0.55 to 6 per million, with higher rates seen with consanguineous marriage.[10] Type 3 vWD manifests with severe bleeding, including excessive mucocutaneous bleeding and musculoskeletal bleeding.

Example of the Presentation and Impact of Type 1 vWD

J.C. is a 26-year-old female who presented with delayed postpartum hemorrhage (PPH) after the delivery of her first child. The pregnancy and delivery had been unremarkable. One week postpartum, the patient began to experience heavy bleeding, necessitating intervention on behalf of the obstetrician in the form of dilation and curettage. At the same time, J.C. was initiated on tranexamic acid, which was continued for 2 weeks. Complete cessation of bleeding occurred at approximately 3 weeks postpartum. This complication led to a referral to a hematologist. A bleeding history was significant for the following: excessive postsurgical bleeding as a child following tonsillectomy and adenoidectomy, which required nasal packing and RBC transfusion; excessive bleeding postdental extractions, requiring consultation with the dentist and repacking; mennorhagia from the time of menarche, which had been well controlled with the combined oral contraceptive pill. There is no family history of vWD. Investigations revealed vWF:Ag 0.45 international units/dL, vWF:RCo 0:39 IU/dL, and FVIII:C 0.60 IU/dL. Multimer gel was unremarkable. A DDAVP challenge demonstrated that the patient was a responder. Finally, ferritin was significantly decreased at 8 mcg/dL, with an associated microcytic anemia (hemoglobin 9.2 g/dL and MCV 72 fL). J.C. was initiated on iron supplementation with resolution of her iron deficiency. She became pregnant again 4 years later. At the time of delivery, she was treated with tranexamic acid and a dose of DDAVP after the cord was clamped. Her postpartum course was uncomplicated.

This case illustrates several important points. First, type 1 vWD is a mild to moderate bleeding disorder. Patients often do not have significant symptoms on a regular basis, or symptoms may be masked/ameliorated by concomitant combined oral contraceptive use, which is common in this patient demographic. A careful bleeding history, focusing on past hemostatic challenges and subsequent complications, is vital in making the diagnosis. A high index of suspicion in required for unusual bleeding complications, such as delayed PPH. The importance of making the diagnosis is highlighted here. With little burden of prophylactic treatment, bleeding complications can be avoided. Finally, women with vWD are at significantly increased risk for iron deficiency with subsequent anemia. This may have a significant impact on energy level and day-to-day physical and cognitive functioning.[160,161] In addition, iron deficiency is a risk factor for postpartum anemia, which itself is associated with impaired quality of life, reduced cognitive abilities, emotional instability, and depression.[162]

Penetrance

In autosomal dominant type 1 vWD, mutations resulting in plasma vWF level less than 25 international units/dL are often fully penetrant, whereas those resulting in higher vWF levels are often incompletely penetrant. Mutations responsible for autosomal dominant types of vWD (2A, 2B, and 2M) are often fully penetrant. Thus in contrast to the variably positive family histories in type 1 vWD, type 2 vWD patients usually have a positive family history.

Laboratory Investigations

The laboratory evaluation for vWD involves a battery of qualitative and quantitative measurements of vWF and FVIII that should be interpreted by a physician with experience in this area given the

Table 140-3 Table of Investigations

vWD Type	vWF:RCo IU/dL*	vWF:Ag IU/dL*	RCo/Ag IU/dL*	FVIII:C IU/dL*	Multimer Pattern†	Other
1	Low	Low	Equivalent	~1.5x vWF:Ag	Normal	
2A	Low	Low	vWF:RCo < vWF:Ag	Low or normal	Abnormal ↓ HMW	
2B	Low	Low	vWF:RCo < vWF:Ag	Low or normal	Abnormal ↓ HMW	↑RIPA‡ (↓ platelet count)
2M	Low	Low	vWF:RCo < vWF:Ag	Low or normal	Normal	
2N	Normal/low	Normal/low	Equivalent	<30	Normal	↓ vWF:FVIIIB§
3	Absent	Absent	NA	<10	Absent	

*Relative to the reference range (approximate values); vWF:RCo (50-200 IU/dL); vWF:Ag (50-200 IU/dL); FVIII:C (50-150 IU/dL).
†*HMW,* High-molecular-weight multimers.
‡Increased agglutination at low concentrations of ristocetin.
§The ability of vWF to bind and protect FVIII is reduced. vWF and FVIII levels can look exactly like those in males with mild haemophilia A or in symptomatic hemophilia A carrier females.

heterogeneity of possible results. Investigations should start with a complete blood count (CBC), along with determination of the activated partial thromboplastin time (aPTT) and prothrombin time (PT). The diagnosis is confirmed with assays of vWF:Ag, vWF:RCo, and FVIII, which are widely available. The last step is a battery of tests to distinguish among the subtypes of vWD (multimer gel electrophoresis, vWF:CB, RIPA, vWF:FVIIIB); these test are only available in specialized laboratories (Table 140-3).

Screening Tests

The CBC may show microcytic anemia as a result of iron deficiency or thrombocytopenia, particularly in type 2B vWD.[93] The aPTT is often normal, but may be prolonged if the FVIII level is reduced below 30 to 40 IU/dL, as can be seen in severe type 1, type 2N, or type 3 vWD. The PT is normal in vWD. Although some laboratories may also include a skin bleeding time and platelet function analysis (PFA closure time) in their evaluation of an individual with suspected vWD, these tests lack sensitivity in persons with mild bleeding or specificity for vWD.[108-110]

Confirming a Diagnosis of vWD

The following specific factor assays should be performed even if the screening tests are normal.[111]

vWF:Ag

This assay determines the quantity of vWF protein (antigen) in the plasma, measured using an enzyme-linked immunosorbant assay (ELISA) or latex immunoassay (LIA). The normal range (which should be determined independently by each laboratory) is approximately 50 to 200 IU/dL.

vWF:RCo

The ristocetin cofactor activity assay determines the capacity of vWF to agglutinate platelets in response to ristocetin. The normal range is approximately 50 to 200 IU/dL.

Factor VIII:C level

Functional FVIII assay determines the activity of FVIII in clot-bound assays. The normal range is approximately 50 to 150 IU/dL.

Normal plasma levels of vWF are approximately 100 IU/dL (100%, corresponds to approximately 10 mcg/mL) with a population range of 50 to 200 IU/dL (50% to 200%). These variations are influenced by a genetic and environmental factors, including ABO blood group (with vWF levels approximately 25% lower in type O individuals), physiologic stressors, and hormones. Several analytic variables also can complicate the diagnosis of vWD.[112] Based on established reference ranges, approximately 2.5% of the normal population will have low vWF levels. In addition, assay variability, particularly for vWF:RCo, renders differentiation of type 1 vWD from type 2 vWD difficult. vWF:RCo and vWF:Ag determined by latex immunoassay have limited sensitivity, which may result in the misdiagnosis of type 3 vWD as type 1 or type 2 vWD. Finally, preanalytic issues with sample handling can lead to decreases in vWF:Ag and vWF:RCo, which can complicate the diagnosis. All of these factors must be considered when interpreting vWF laboratory results and at least two sets of tests using fresh samples are needed to confirm the diagnosis of vWD. In addition, diagnostic testing should be avoided in stressed, ill, or pregnant patients (see box on Factors to Consider When Interpreting vWD Results).

Discriminating Tests to Identify vWD Subtype

vWF Multimer Analysis

SDS-agarose electrophoresis is used to assess vWF oligomers in plasma[113] (Fig. 140-6). Normal plasma contains multimers composed of over 40 vWF dimers. Multimers are classified as high, intermediate, or low molecular weight (HMW, IMW, LMW, respectively) by counting bands 1 to 5 as LMW, 6 to 10 as IMW and those above 10 as HMW (see www.isth.org/default/index.cfm/publication/ssc-minutes). HMW multimers are decreased or missing in types 2A and 2B vWD, and IMW multimers may also be absent in type 2A vWD. Abnormalities in satellite ("triplet") band patterns provide clues about pathogenesis and help to subclassify type 2A vWD, including IIA, IIC, IID, and IIE—for example, type 2A(IIE).[111,114]

Factors to Consider When Interpreting vWD Results

	Considerations	*Results*
Preanalytical	When was the sample collected and processed? Is there a significant length of time for travel/batching results before samples are run? Are they frozen in a timely fashion?	vWF:RCo may be decreased and result in a false-positive for type 2
Analytical	Convention of established references	False-positive diagnosis of vWD in 2.5% of population
	High degree of assay variability, particularly for vWF:RCo	False-positive diagnosis of type 2 in a type 1 patient may result in the misdiagnosis of type 3 for type 1 or type 2 vWD
	A high lower limit of detection (LOD) for certain vWF:Ag and vWF:RCo assays, in particular LIA-based assays	
Patient Factors	Drugs (OCP, HRT, or valproic acid)	False negative or positive
	ABO type	False negative
	Pregnancy	Reversible acquired von Willebrand syndrome (AvWS)
	Hypothyroidism	
	Comorbid illness (e.g., valvular heart disease, lymphoma)	

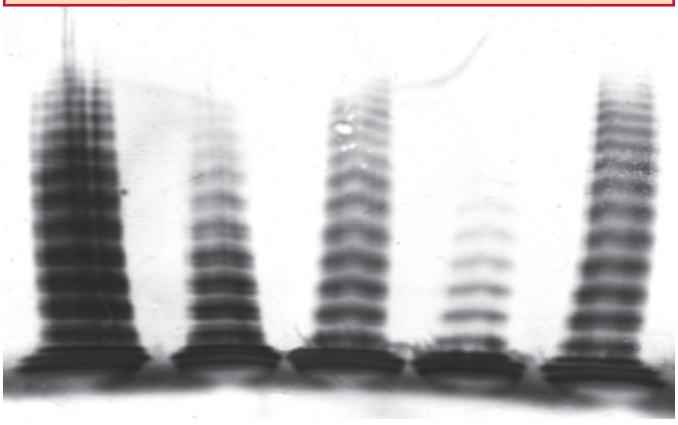

Figure 140-6 EXAMPLE OF A MULTIMER ANALYSIS. Lane 1 represents normal plasma multimer patterns. Lanes 2 and 4 show the plasma vWF multimer analysis for patients with type 2A and type 2B vWD, respectively. Both show variable loss of HMW multimers. On the other hand, lanes 3 and 5 represent type 1 patients and demonstrate the presence of HMW multimers and an overall decrease in vWF.

Ristocetin-Induced Platelet Aggregation

The RIPA assay tests the capacity of vWF to agglutinate platelets at varying concentrations of ristocetin. Agglutination with low concentrations of ristocetin (approximately 0.5 mg/mL) may indicate type 2B vWD or its phenocopy, platelet-type pseudo vWD (PT-vWD), resulting from mutations in GPIBA, in which enhanced vWF-platelet binding is present.[11,115] In contrast to the vWF:RCo (which evaluates the interaction between the patient's vWF and formalin-fixed platelets), the RIPA assay evaluates the sensitivity of the patient's platelets to low-dose ristocetin. In cases of type 2B or platelet-type vWD, the platelet membrane is "overloaded" with high-affinity mutant vWF, resulting in platelet agglutination at low ristocetin concentrations.[91] In some cases of type 2B vWD, all variables except RIPA may be normal.[116,117] RIPA should be normal in type 1 vWD unless vWF levels are below 10 to 20 units/dL.

Binding of FVIII by vWF (vWF:FVIIIB)

This test determines the ability of vWF to bind FVIII[118,119] and is useful for the diagnosis of type 2N vWD.[98] There are no standard units for the output of this test.

Collagen Binding Assay (vWF:CB)

This test determines the ability of vWF to bind to collagen and is dependent on HMW vWF multimers. Consequently, the test helps to identify functional vWF discordance (i.e., to distinguish between types 1 and 2 vWD). Reduced collagen binding reflects the loss of HMW multimer forms[120] (type 2A vWD) or can reflect a specific collagen-binding deficiency (type 2M vWD). The normal range is approximately 50 to 200 IU/dL.

vWF Propeptide/Antigen Ratio (vWFpp/vWF:Ag)

An increased ratio of steady-state plasma vWFpp to vWF:Ag identifies patients with mutations that increase vWF clearance.[61] The mean ratio in normal individuals is 1.3, with a normal range of 0.54 to 1.98.

Desmopressin (DDAVP) Responsiveness

DDAVP administration releases vWF stores from endothelial cells. The pattern of DDAVP response in vWD subtypes (Table 140-4) may help to assign vWD subtype.[112] In addition, a decrease in the duration of DDAVP response may indicate an increased clearance mutation.

Genotyping

The identification of a mutation is not necessary for the diagnosis of vWD. However, genotyping should be considered when specialized testing with the vWF:FVIIIB assay is unavailable and type 2N vWD is suspected. Genotyping is also useful to discriminate between type 2B vWD and platelet-type vWD for prenatal assessment and alloantibody risk assessment in type 3 vWD. In mild-type 1 vWD, the likelihood of finding a mutation is low because mutations are not localized to a particular domain or exon and the results are of little clinical utility. A recent guideline on vWD genetic testing has been published by the UK Haemophilia Centre Doctors Organisation.[121]

Differential Diagnosis

Hemophilia A

Both type 2N vWD and mild hemophilia A (caused by mutations in F8) result in reduced levels of FVIII:C (approximately 5-40 IU/dL) with normal or borderline low levels of vWF. Although the vWF:FVIIIB test distinguishes between the two disorders,[122] the test is not widely available and the results may be equivocal.

Table 140-4 DDAVP Responsiveness in the Various Subtypes of vWD

vWD Type	vWF:RCo	vWF:Ag	RCo/Ag	FVIII:C International Units/dL	vWF:CB	vWF:CB/vWF:Ag
1	Increase	Increase	Remains >0.7	Increase	Increase	Remains >0.7

Modified from Favaloro EJ: Rethinking the diagnosis of von Willebrand disease. *Thromb Res* 2:17, 2011.

In families with reduced FVIII:C, an X-linked pattern of inheritance helps identify those with mild hemophilia A. When family history is uninformative and vWF levels and function are normal, it may be preferable to perform sequence analysis of F8 before vWF, even in symptomatic females who are simplex cases (i.e., a single occurrence in a family), because F8 mutation and skewed X-chromosome inactivation (lyonization) are often responsible for symptoms. In these cases, F8 intrachromosomal inversions may be sought and DNA sequence analysis or mutation scanning of F8 exons 1-26 undertaken.[123,124] In females, dosage analysis using MLPA can also be used to identify heterozygous partial or complete gene deletions or duplications. F8 mutations may be detected in more than 50% of cases referred for "possible 2N vWD or hemophilia A." When F8 mutations are absent, or if vWF level and function are also abnormal, vWF can be analyzed.

Platelet-Type vWD

Platelet-type pseudo vWD (PT-vWD, also called *pseudo vWD*) mimics type 2B vWD but is caused by mutations in *GPIBA*. The disorders can be distinguished by mixing patient platelets or plasma with control plasma or platelets and using aggregometry or flow cytometry to identify the defective compound. However, these assays are technically challenging.[113,125-127] In the absence of mutations in exon 28 of vWF, mutations in exon 2 of *GPIBA* may be identified in approximately 10% of persons misdiagnosed with type 2B vWD. To date, missense mutations reported to affect GpIbα include p.Gly249 and p.Met255 plus a 27bp in-frame deletion p.Pro449_Ser457del (c.1345_1371del27).[128] The PT-vWD registry is available at www.pt-vwd.org/. PT-vWD is probably underdiagnosed. Misdiagnosis of PT-vWD may result in ineffective treatment of patients. vWF concentrate is needed to correct the reduced vWF level, but platelet transfusion may also be required if there is significant thrombocytopenia.[115] The half-life of replaced vWF is reduced in PT-vWD because of binding to abnormal GpIbα. Consequently, vWF concentrate must be administered more frequently.

Acquired von Willebrand syndrome (AvWS)

This mild to moderate bleeding disorder is a result of an acquired deficiency or dysfunction of vWF.[129-131] Exclusion of a lifelong personal and family history of bleeding is an important aspect of the diagnosis. The prevalence of AvWS has not been established. Although AvWS was thought to be uncommon, cohort studies suggest that the prevalence may be significantly underestimated. For example, when selected patient populations were screened, approximately 10% of patients with hematologic disorders,[132] approximately 79% with aortic stenosis,[133] and up to 100% with left ventricular assist devices were diagnosed with AvWS.[134-136] The median age of diagnosis is 62 years, but the disorder may occur in any age group (range 2 to 96 years).[137] AvWS has diverse pathology and may result from autoantibodies that impair vWF function or increase its clearance, adsorption of HWM vWF multimers to malignant cells or platelets, proteolytic cleavage of vWF after shear stress-induced unfolding, or decreased synthesis. Diseases that have been implicated include (1) lymphoproliferative disorders and plasma cell dyscrasias, including monoclonal gammopathy of unknown significance, multiple myeloma, and Waldenstrom macroglobulinemia; (2) autoimmune disorders, including systemic lupus erythematosus, scleroderma, and antiphospholipid antibody syndrome; (3) aortic stenosis and ventricular septal defects, which can trigger shear-induced conformational changes that increase vWF proteolysis; (4) thrombocytosis, including essential thrombocythemia or other myeloproliferative disorders that lead to a type 2 phenotype; (5) Wilms tumor or lymphoproliferative disorders that can be associated with increased vWF clearance by aberrant binding to tumor cells; (6) decreased vWF synthesis, for instance, with hypothyroidism; and (7) drugs including valproic acid, ciprofloxacin, griseofulvin, and hydroxyethyl starch.[138] The treatment goals can be divided into two categories: treatment or prevention of bleeding or induction of long-term remission. The agents used for prevention and treatment of bleeding in AvWS overlap with those used in vWD and include DDAVP or vWF-containing concentrates, which can transiently increase vWF levels. Other options include recombinant factor VIIa, antifibrinolytic agents, IVIG, or plasmaphoresis for AvWS associated with monoclonal gammopathies. Often a combination of agents is required to effect hemostasis. Whenever possible, treatment of the underlying disorder should be considered and may result in remission of the AvWS.

Management of vWD

The approach to the management of vWD is summarized in Fig. 140-7.

Evaluations Following Initial Diagnosis

To establish the extent of disease in an individual diagnosed with vWD, the following evaluations are recommended: (1) a personal and family history of bleeding to help predict severity and tailor treatment (use of a standardized bleeding assessment tool can be helpful)[139-141]; (2) a joint and muscle evaluation for those with type 3 vWD (musculoskeletal bleeding is rare in types 1 and 2 vWD); (3) screening for hepatitis B and C, as well as HIV if the diagnosis is type 3 vWD or if the individual received blood products or plasma-derived clotting factor concentrates before 1985 (this screening should be followed by vaccinations for hepatitis A and B)[130]; (4) determination of serum iron and ferritin (to assess iron stores), because many individuals with vWD are iron deficient, particularly women with menorrhagia; and (5) gynecologic evaluation for women with menorrhagia.[142] Individuals with vWD benefit from referral to a comprehensive bleeding disorders program for education, treatment, and genetic counseling. In addition, individuals with type 3 vWD should have periodic evaluations by a physiotherapist to monitor joint mobility.

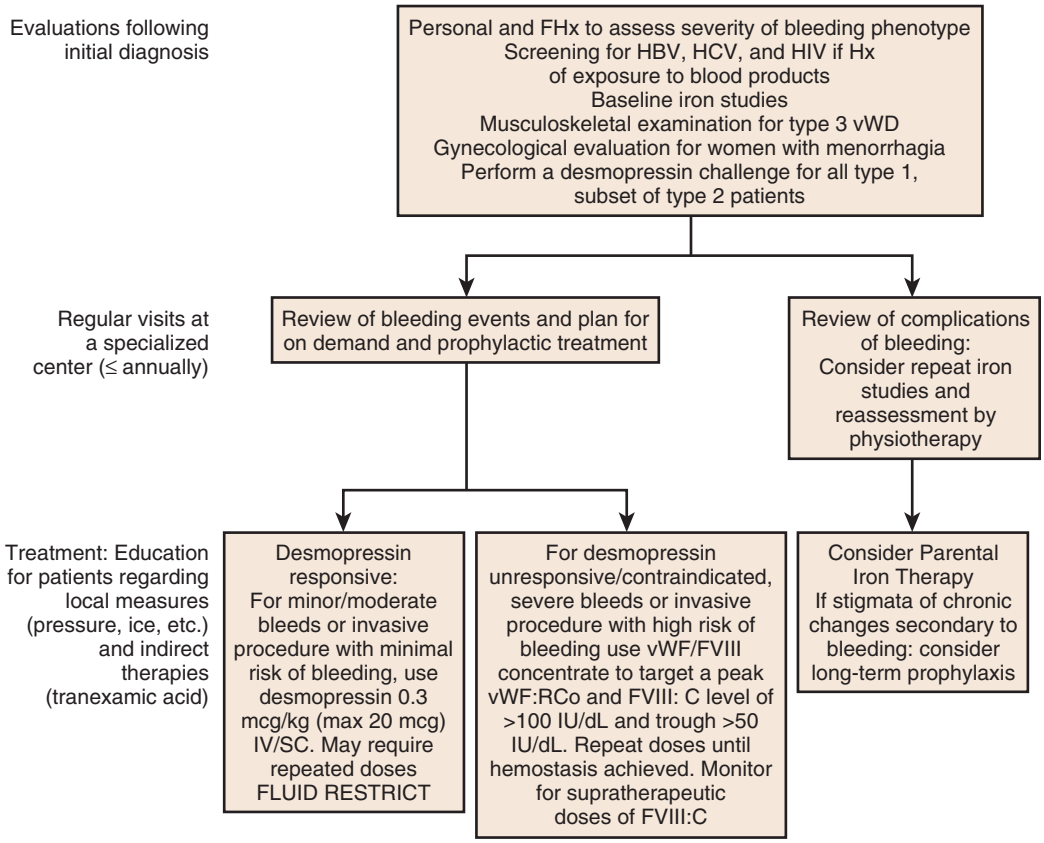

Figure 140-7 APPROACH TO THE MANAGEMENT OF vWD.

Treatment of vWD

In general, the management of vWD can be divided into three main categories: (1) localized measures to stop or minimize bleeding; (2) pharmacologic agents that provide indirect hemostatic benefit; and (3) treatments that directly increase plasma vWF and FVIII levels. Individuals with vWD should receive prompt treatment for severe bleeding episodes.

Localized Measures

The importance of localized measures to control bleeding in vWD, such as the application of direct pressure to a site of bleeding or injury, should not be understated. Biting down on a piece of gauze may halt bleeding from a tooth socket, and application of a compression bandage and cold pack to an injured limb may reduce subsequent hematoma formation. Management of nosebleeds can be particularly problematic for some affected children, and patients may benefit from a step-wise action plan that escalates from pressure to packing after a certain time period, including guidelines regarding how long to wait before seeking medical attention. In selected cases, nasal cautery may be required for prolonged or excessive epistaxis.

A number of topical hemostatic agents that are predominately used to achieve surgical hemostasis may have a limited role in the treatment of vWD and bleeding; these include gelatin foam/matrix, topical thrombin and fibrin sealants.

Indirect Therapies

A number of adjunctive therapies are of benefit in vWD, particularly at the time of minor surgical and dental procedures and to treat menorrhagia. Fibrinolytic inhibitors (e.g., tranexamic acid), which inhibit the conversion of plasminogen to plasmin, can be helpful for treatment or prevention of bleeding episodes.[11] These agents can be used either as sole therapy or as adjuncts to DDAVP or vWF/FVIII concentrates and may be particularly useful to control mucosal bleeding in the oral cavity or gastrointestinal or genitourinary tracts. The most common adverse events to tranexamic acid are gastrointestinal side effects and headache. Tranexamic acid is contraindicated in disseminated intravascular coagulation and bleeding from the upper urinary tract, where it can lead to urinary tract obstruction by clots. Hormonal treatments (i.e., the combined oral contraceptive pill) are effective for the treatment of menorrhagia. Nonmedical treatments, such as levonorgestrel-releasing intrauterine systems or endometrial ablation, may be useful in selected patients with vWD. A consensus document on the management of women with vWD was recently published.[142]

Desmopressin

Most individuals with type 1 vWD and some with type 2 vWD respond to intranasal, intravenous or subcutaneous treatment with desmopressin,[143,144] which promotes release of stored vWF and raises levels 3- to 10-fold. Peak effects are achieved 30 and 90 minutes after intravenous and intranasal delivery, respectively. The usual parenteral dose is 0.3 mcg/kg (maximum dose 20 mcg) infused in approximately 50 mL of normal saline over approximately 30 minutes. The dose of the highly concentrated intranasal preparation is 150 mcg for children under 50 kg and 300 mcg for larger children. It is important to note that highly concentrated products, (e.g., Stimate), deliver 150 mcg per spray, a much higher concentration than that used to treat enuresis.

After vWD diagnosis, a desmopressin challenge is advisable to assess vWF response. vWF and FVIII levels should be determined before and at several points after desmopressin administration (e.g., at baseline and at 1, 2, and 4 hours). A threefold increase in vWF and FVIII levels to at least 0.30 IU/mL (30%) is usually considered adequate for situations such as dental procedures, minor surgery, or

the treatment of epistaxis or menorrhagia. Significantly decreased vWF:Ag or vWF:RCo at the 4-hour point may indicate a vWD phenotype with increased clearance. In such cases, the desmopressin response may be too transient to be of benefit.

Desmopressin is safe and generally well tolerated. Common side effects include facial flushing and headache. Tachycardia, lightheadedness and mild hypotension can occur. The most serious side effects are severe hyponatremia and seizures.[145] Reduction of fluid intake for 24 hours after DDAVP administration is an important precaution to prevent water intoxication. In patients receiving repeated desmopressin administrations, serum sodium levels should be monitored. Desmopressin should be used with caution in those younger than 2 years of age because of a higher risk for hyponatremia. Desmopressin is contraindicated in individuals with atherosclerotic disease and in those over 70 years of age; vWF/FVIII concentrate should be used in these patients. In persons who are intolerant to desmopressin or have a poor vWF response, clotting factor concentrate is required.

An important limitation in the use of desmopressin is the development of tachyphylaxis with repeated administration. When given repeatedly at intervals of less than 24 hours, the magnitude of the vWF and FVIII increments can fall to approximately 70% of that obtained with the initial dose.[146] For practical purposes, a single dose of desmopressin before dental extractions or minor procedures is usually sufficient. Although repeated doses can be given at 12 or 24 hours, the potential for tachyphylaxis must be considered. Additionally, in situations where repeat dosing is considered, more prolonged fluid restriction is required.

Most type 1 vWD patients respond adequately to desmopressin, type 3 vWD patients typically do not respond to this drug, and the response in type 2 vWD patients respond is variable. Type 2A patients often exhibit an adequate response and may benefit from a desmopressin trial. Type 2M patients typically do not respond well to desmopressin. Although desmopressin is generally contraindicated in type 2B vWD because of the transient thrombocytopenia that accompanies the release of mutant vWF, it is effective and can be considered on an individualized basis.[147,148] Desmopressin produces a two- to ninefold increase in vWF and FVIII in patients with type 2N vWD, but the increase in FVIII only persists for approximately 3 hours.[149] Therefore desmopressin should be reserved for situations in which a transient rise in FVIII is sufficient.

vWF/FVIII Concentrates

vWF/FVIII concentrates are required for patients who do not have an adequate response to desmopressin, those who experience side effects, or those have contraindications to desmopressin. Because of tachyphylaxis with desmopressin, patients with severe bleeding or those requiring major or repeated surgery often need vWF replacement therapy. Purified, viral-inactivated, plasma-derived vWF/FVIII are the products most frequently used (e.g., Humate-P, Wilate). The quantity of ristocetin cofactor activity (vWF:RCo) relative to factor VIII:C varies by product; Humate-P contains 2.4 vWF:RCo units for each 1 FVIII:C unit,[150] whereas Wilate contains a 1:1 ratio.[151] Both products contain a full spectrum of vWF multimers, including HMW multimers, and closely resemble normal plasma.[152] Highly purified FVIII concentrates (monoclonal antibody purified and recombinant) should not be used to treat vWD because they lack vWF.

Dosing recommendations are provided either in vWF:RCo (North America) or FVIII:C (Europe) units and are weight-based; repeat infusions can be given every 12 to 24 hours, depending on the clinical situation. The goal is to maintain vWF:RCo and FVIII:C at more than 100 IU/dL at peak and at more than 50 IU/dL at trough until hemostasis is achieved. With vWF/FVIII concentrates, the FVIII:C response is higher and more sustained than predicted from the dose because of the stabilizing effect of exogenous vWF on endogenous FVIII.[153] Details regarding dosing can be found in the product inserts. vWF:RCo and FVIII:C levels should be measured in patients receiving repeat infusions, not only to ensure adequate hemostasis but also to monitor for supraphysiologic levels of FVIII because thromboembolic events have been associated with high FVIII levels. The overall incidence is very low, and most cases occurred in surgical patients with other risk factors.[154] Therefore, mechanical and medical thromboprophylaxis should be considered on an case-by-case basis. Adverse reactions to vWF/FVIII concentrates are rare but include allergic and anaphylactic symptoms, such as urticaria, chest tightness, rash, pruritus and edema.[155]

vWF:FVIII concentrates are effective in over 97% of events.[150] In the rare event that infusion of a vWF/FVIII concentrate is ineffective at stopping bleeding, transfusion of platelet concentrates may be beneficial, presumably because they facilitate the delivery of small amounts of platelet vWF to the site of vascular injury.[11]

Prophylaxis

Short-term prophylaxis with a combination of an antifibrinolytic, desmopressin, and vWF/FVIII concentrates, in anticipation of a defined bleeding challenge, such as surgery, is the standard of care in the treatment of vWD. The role of long-term continuous prophylaxis, defined as primary if initiated before long-term sequelae have developed (e.g., joint damage) or secondary if initiated after the development of chronic changes, is less established in vWD than it is in severe hemophilia. Individuals with severe cases of vWD, in particular type 3 vWD and certain patients with severe type 1 or type 2 vWD, may experience significant joint bleeds with resultant hemophilic-like arthropathy, as well as severe and frequently recurrent nasal/oral, gastrointestinal, or menstrual bleeding. The resultant anemia, hospitalizations, and absences from school or work may have a significant impact on quality of life. Although there is limited evidence, several cohort and case studies[156-158] suggest that both primary and secondary long-term prophylaxis improve quality of life (by reducing the frequency of bleeding episodes or the need for transfusions), alleviate anemia, reduce hospitalizations, and prevent chronic joint disease. Complications are unusual aside from rare cases of vWF inhibitor formation (approximately 3%). Controversy exists about the specific indications, schedules, and dosing of prophylactic regimens. This is the subject of an ongoing international trial, known as the vWD International Prophylaxis (VIP) trial, which began recruitment of patients in 2007.

Pediatric Issues

Prenatal diagnosis for pregnancies at increased risk (generally only for type 3 vWD) is possible by analysis of DNA extracted from fetal cells obtained by chorionic villus sampling (CVS) at 11 to 13 weeks of gestation or amniocentesis, which is usually performed at 15 to 18 weeks of gestation. The disease-causing allele(s) of an affected family member must be identified before prenatal testing. Preimplantation genetic diagnosis (PGD) may be available for families in which the disease-causing mutation(s) have been identified.[159]

The diagnosis and care of infants and children with vWD requires special consideration. An accurate assessment of hemorrhagic symptoms is a key component in the diagnosis of vWD, but it often presents a significant challenge in the pediatric population. Bruising and epistaxis are common among children with vWD, but these symptoms are also reported by children without vWD. In addition, the classical symptoms of vWD in adults (e.g., menorrhagia, postsurgical bleeding) are clearly not prevalent in the pediatric population. Because a child may not have encountered many hemostatic challenges and may be prepubertal, the bleeding history may be unimpressive. The effect this negative history may have on perceived risk for bleeding is highlighted in two of the previously published bleeding scores,[139,140] which assign a negative value to lack of bleeding symptoms and are based on the accumulation of bleeding symptoms or complications. With a goal of addressing these issues, increasing interest exists in the development of new clinical tools for quantifying bleeding in the pediatric population.[141] Finally, the initial diagnostic

Assessment of a Neonate

A baby boy was born to a mother with known type 2B vWD. On the day of birth, investigations were performed and demonstrated the following: vWF:Ag 78 IU/dL, vWF:RCo 61 IU/dL, and FVIII:C 0.69 IU/dL. The mother was informed that the results were all within normal range and that her newborn infant was not affected by type 2B vWD. At approximately 18 months of age, the mother presented with her toddler boy with the complaint of excessive mucocutaneous bleeding. Blood work at that time demonstrated: vWF:Ag 50 international units/dL, vWF:RCo 20 international units/dL, and FVIII:C 51 international units/dL. Multimer analysis revealed an abnormal profile with a doublet patter. Finally, genotyping revealed that the boy was heterozygous for the same mutation, R1306W, that his mother carried.

This case illustrates several important points. Neonatal levels of vWF are increased over baseline; if investigations are performed, they should be interpreted using appropriate reference ranges. Alternatively, if a phenotypic diagnosis is being sought, it is preferable to postpone investigations, decreasing the likelihood of pretest analytical variables, such as difficulty in collecting an appropriate blood sample from a neonate, and the difficulties with interpretation of the results. Finally, in cases in which the mutation is known, genotyping is diagnostic and also the most straightforward.

assessment of an infant is complicated by the fact that vWF levels are higher in the neonatal period. Consequently, phenotypic testing of vWD should be delayed until later in childhood (see Fig. 140-7).

Desmopressin should be avoided in children younger than the age of 2 because of the potential difficulty in restricting fluids. Infant males should be circumcised only after consultation with a pediatric hemostasis specialist. Children with vWD may also experience bruising after routine immunizations and gum bleeding following the loss of primary teeth. Typically, only patients with type 3 vWD experience spontaneous musculoskeletal bleeding, such as that seen in patients with severe hemophilia, and should be considered for long-term prophylaxis with vWF/FVIII concentrates, as discussed in the preceding section (see box on Assessment of a Neonate).

CHAPTER 141

DISSEMINATED INTRAVASCULAR COAGULATION

Marcel Levi

A variety of disorders, including infectious or inflammatory conditions and malignant disease, lead to activation of coagulation. In many cases, this activation of coagulation will not lead to clinical complications and is not even detected by routine laboratory tests but can only be measured with sensitive molecular markers for activation of coagulation factors and pathways.[1,2] However, if activation of coagulation is sufficiently strong, the platelet count may decrease, and global clotting times may become prolonged. In its most extreme form, systemic activation of coagulation is known as disseminated intravascular coagulation (DIC). DIC is characterized by the simultaneous occurrence of widespread (micro)vascular thrombosis, thereby compromising blood supply to various organs, which may contribute to organ failure.[3,4] Because of ongoing activation of the coagulation system and other factors, such as impaired synthesis and increased degradation of coagulation proteins and protease inhibitors, consumption of clotting factors and platelets may occur, resulting in bleeding from various sites.

In view of the multiple, often contrasting mechanisms that occur in patients with DIC, a consensual definition of DIC had been a matter of debate. In 2001, the subcommittee on DIC of the International Society on Thrombosis and Hemostasis (ISTH) proposed a definition that reflects the central role of the microvascular milieu (i.e., endothelial cells, blood cells, and the plasma protease system) in the pathogenesis of DIC. This definition of DIC reads as follows: "DIC is an acquired syndrome characterized by the intravascular activation of coagulation without a specific localization and arising from different causes. It can originate from and cause damage to the microvasculature, which if sufficiently severe, can produce organ dysfunction."[5]

The diagnosis of DIC may be hampered by the nonspecific nature of many indicators of coagulation activation, although newly developed scoring algorithms based on readily available routine laboratory parameters show promising diagnostic accuracy.[5] Owing to the complexity of the clinical presentation, the variable and unpredictable course, and the multitude of therapies given to patients with DIC, properly conducted clinical trials are difficult to perform and even to devise. Management relies on limited evidence from clinical trials in combination with small studies using surrogate outcome endpoints and experience from case series, as well as from an understanding of the underlying pathophysiologic mechanisms.[6]

EPIDEMIOLOGY

Activation of coagulation in concert with inflammatory activation can result in microvascular thrombosis, which contributes to multiple organ failure in patients with severe sepsis.[7] In support of this concept, postmortem findings in patients with coagulation abnormalities and DIC on the background of severe sepsis include diffuse bleeding, hemorrhagic necrosis of tissues, microthrombi in small blood vessels, and thrombi in midsize and larger arteries and veins. Ischemia and necrosis were invariably the result of fibrin deposition in small- and midsize vessels. Importantly, intravascular thrombi appear to be the driver of the organ dysfunction. Fibrin deposition in various organs also is a characteristic finding in animal models of DIC. Thus experimental bacteremia or endotoxemia causes intra- and extravascular fibrin deposition in the kidneys, lungs, liver, brain, and other organs. Amelioration of the hemostatic defect by various interventions in these models reduces fibrin deposition; improves organ fraction; and, in some cases, reduces mortality. Finally, results of clinical studies also support the concept that activation of coagulation is as important a determinant of clinical outcome. DIC has shown to be an independent predictor of organ failure and mortality.[8] In a consecutive series of patients with severe sepsis, 43% of patients with DIC were compared with 27% in those without DIC. In this study, the severity of the coagulopathy was also directly related to mortality.[9]

In addition to microvascular thrombosis and organ dysfunction, coagulation abnormalities may have other harmful consequences. Thrombocytopenia in patients with sepsis places them at an increased risk of bleeding. For example, critically ill patients with a platelet count of below 50×10^9/L have a four- to fivefold higher risk for bleeding than those with higher platelet counts.[10] Although the overall risk of intracerebral bleeding in patients in the intensive care unit (ICU) is less than 0.5%, up to 88% of patients with this complication have platelet counts less than 100×10^9/L. The use of anticoagulants in patients with thrombocytopenia further increases the risk of bleeding. Regardless of the cause, multivariate analyses indicate that thrombocytopenia is an independent predictor of ICU mortality and increases the risk of death by 1.9- to 4.2-fold. In particular, thrombocytopenia that persists more than 4 days after ICU admission or 50% of greater decrease in platelet count during the ICU stay is associated with a four- to sixfold increase in mortality. In fact, the platelet count appears to be a stronger predictor for ICU mortality than composite scoring systems, such as the Acute Physiology and Chronic Evaluation (APACHE) II or Multiple Organ Dysfunction Score (MODS). Decreased levels of coagulation factors, as reflected by prolonged global coagulation times, also increase the risk of bleeding. Prolongation of the prothrombin time (PT) or activated partial thromboplastin time (aPTT) to over 1.5 times the control is associated with an increased risk of bleeding and mortality in critically ill patients.

PATHOBIOLOGY

Traditionally, DIC was thought to be the result of activation of both the extrinsic and intrinsic pathways of coagulation. The classical concept was that the extrinsic pathway was initiated by a tissue-derived component, which activated factor VII, leading to the direct conversion of prothrombin to thrombin. This process would proceed as long as there was tissue damage from systemic infection, trauma, solutio placentae, or malignancy. In contrast, the intrinsic or contact pathway of coagulation was initiated by contact activation of factor XII, which, together with its cofactors, kallikrein and kininogen, then activated factor XI with subsequent activation of factor IX. The initiators of contact activation were poorly understood until recently but were thought to include collagen and artificial surfaces. In recent years, the molecular mechanisms of coagulation pathways have been defined (Fig. 141-1). This has provided new insight into the

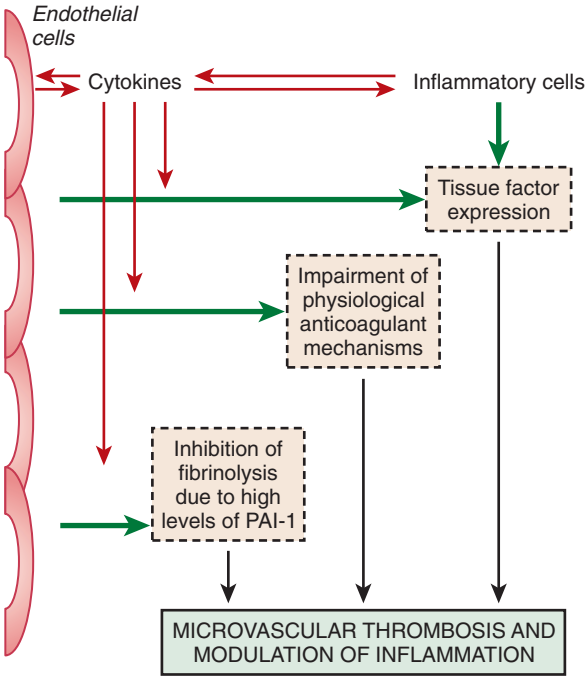

Figure 141-1 PATHOGENESIS OF DISSEMINATED INTRAVASCULAR COAGULATION (DIC). Pathways involved in the activation of coagulation in DIC. Both perturbed endothelial cells and activated mononuclear cells may produce proinflammatory cytokines that induce tissue factor expression, thereby initiating coagulation. In addition, downregulation of physiological anticoagulant mechanisms and inhibition of fibrinolysis promotes intravascular fibrin deposition. *PAI-1,* Plasminogen activator inhibitor, type 1.

pathogenesis of DIC. In general, current thinking is that thrombin and fibrin generation in patients with DIC is largely driven via the extrinsic pathway; the role of the contact system is uncertain.

Tissue Factor–Factor VII(a) Pathway

The extrinsic pathway is initiated by the tissue factor (TF)–factor VIIa complex. TF is a membrane-bound 4.5-kD protein that is constitutively expressed on cells that are mostly in tissues not in direct contact with blood, such as the adventitial layer of larger blood vessels.[11] Subcutaneous tissue also contains substantial amounts of TF. When expressed on the cell surface, TF interacts with factor VII, either in its zymogen or activated form. The TF–factor VIIa complex catalyzes the activation of both factor IX and factor X. Factors IXa and Xa enhance the activation of factors X and prothrombin, respectively. In cells in contact with the blood circulation, TF is induced by the action of mediators such as cytokines, C-reactive protein, and advanced glycosylation end products. Inducible TF is predominantly expressed by monocytes and macrophages. Monocyte TF expression is enhanced in the presence of platelets and granulocytes in a P-selectin dependent fashion. This may reflect nuclear factor kappa-B (NFκB) activation that occurs when activated platelets bind to neutrophils or mononuclear cells. These cell–cell interactions also stimulate the production of interleukin-1b (IL-1b), IL-8, MCP-1, and tumor necrosis factor-α (TNF-α). Under cell culture conditions, cytokines such as TNF-α, and IL-1, can induce TF expression by vascular endothelial cells, but the in vivo relevance of this finding is uncertain. Studies in vivo suggest that IL-6 is the dominant mediator of TF expression by mononuclear cells.

Increased monocyte TF expression and procoagulant activity have been demonstrated in DIC associated with sepsis, cancer, or coronary disease. Tissue expression of TF appears to be localized to certain organs and vascular beds, but it is uncertain whether its expression is under genetic control in an organ-specific fashion. With trauma, such as extensive surgery, brain injury, or burns, it is likely that constitutively expressed TF at the site of injury is the primary source of procoagulant material, but direct support for this concept is lacking.

The Intrinsic Pathway

The role of the intrinsic pathway in the pathogenesis of DIC is uncertain. Negatively charged substances, such as phospholipids, polyphosphates, and glycosaminoglycans, are potential activators of the contact pathway. Studies in patients with suspected DIC have identified elevated levels of markers of activation of the contact system. In patients with meningococcal septicemia, there was a negative correlation between plasma factor XII levels and factor XIIa–C1 inhibitor complexes. Although this finding implies consumption of factor XII and subsequent downstream activation of factor XI, an alternative explanation is that there is a negative acute phase effect with reduced synthesis of factor XII in conjunction with thrombin-mediated activation of factor XI.

However, blockade of the contact system with a factor XIIa-directed antibody failed to prevent DIC in a balloon model of *Escherichia coli* sepsis but diminished development of lethal hypotension. These findings provide reasonable support for the current view that the contact pathway does not contribute to DIC but may play important roles in proinflammatory mechanisms related to vascular permeability, vascular proliferation (kininogen induces smooth muscle cell proliferation), and enhancement of fibrinolysis.[12]

Cytokines and Other Amplification Pathways

Activation of blood coagulation requires several cofactors. For development of DIC, the surfaces of cell remnants or intact cells, inflammatory mediators, and coagulation proteins are required. The stimulus for activation depends on the underlying disease and may range from bacterial cell compounds, such as endotoxin, TF on host or cancer cells, other cancer cell procoagulants, or fat or amniotic fluid emboli by unknown pathways. Each of these triggers interacts with other mediators: TF assembles on anionic phospholipid surfaces, which can be provided by activated platelets, leukocytes, or cancer cells, and cytokines interact with receptors and induce signaling pathways that induce TF expression and other proinflammatory components via the NFκB complex.

Endotoxin is a lipopolysaccharide compound of gram-negative bacteria that induces the sepsis syndrome and DIC. Gram-negative bacteria liberate endotoxins from their membrane, which interact with cell surfaces via various pathways. In blood, endotoxin directly binds to CD 14 on monocytes and binds to endothelial cells after complexing with lipopolysaccharide binding protein (LBP) and the Toll-like receptor 4 (TLR 4) complex. Through these interactions, endotoxin induces signaling pathways that culminate in NFκB activation and initiates the expression of proinflammatory cytokines and TF. Likewise, exotoxins, such as lipoteichoic acid (LTA) from gram-positive bacteria, can induce proinflammatory cytokine expression in a similar fashion.

The molecular mechanisms underlying endotoxin-induced activation of coagulation have been studied in primates and baboons. In endotoxin or *E. coli* models of sepsis, inhibition of the TF pathway abolishes the activation of coagulation, highlighting the importance of TF. IL-6 is an important mediator of procoagulant effects, and TNF-α is involved in the fibrinolytic response to endotoxin. Inhibition of TF with TFPI reduces IL-6 levels in the baboon model, suggesting that there is extensive crosstalk between coagulation and inflammatory mediators (see later discussion). Monocytes that express TF bind factor VII(a), shed TF, or bind to the damaged vessel wall. After interacting with platelets, circulating monocytes may trigger DIC. Microvesicles may accelerate this process, and the complex interaction among cells, membrane fragments, soluble mediators, and

proteins may trigger the DIC syndrome. The severity and duration of the consumptive process are mainly determined by the potency of the triggers and the capacity of inhibitory mechanisms.

Cross-Talk Among Coagulation Proteases Results in Proinflammatory Effects

In addition to activating coagulation protein zymogens, coagulation proteases also interact with specific cell receptors and trigger signaling pathways that elicit proinflammatory mediators.[7] Factor Xa, thrombin and the factor VIIa–TF complex have such effects. Factor Xa injection into rats induces localized inflammation, probably as a result of its interaction with effector cell protease receptor-1 (EPR-1) and not because of thrombin generation. Exposure of cultured endothelial cells to factor Xa stimulates the production of monocyte chemotactic protein 1 (MCP-1), IL-6, and IL-8 and upregulates the expression of adhesion proteins that tether neutrophils to the cell surface. Further evidence for the crosstalk between inflammation and coagulation comes from the observations that IL-6 and IL-8 elicit TF-dependent procoagulant activity in monocytes, and IL-6 has been identified as the critical mediator of procoagulant activity either on its own or after endotoxin challenge in vivo. Therefore, cytokine production induced by factor Xa may be an important driver of coagulation in DIC.

In addition to its procoagulant functions, thrombin has a variety of noncoagulant effects. Thrombin induces the release of MCP-1 and IL-6 from fibroblasts, epithelial cells, and mononuclear cells in vitro. Thrombin also induces IL-6 and IL-8 production in endothelial cells. When generated in whole blood, IL-8 production has a procoagulant effect that is TF dependent. Cell activation by thrombin is likely mediated by protease-activated receptor (PAR). The factor VIIa–TF complex also activates cells by binding PAR 2.

Direct evidence of the in vivo relevance of these phenomena comes from a study showing that recombinant factor VIIa infusion in volunteers induces an increase in plasma levels of IL-6 and IL-8. Although the concentrations of factor VIIa infused far exceed those found in patients with sepsis, it is possible that factor VIIa–induced cytokine production is of physiological importance. Thus this information adds to the concept that several coagulation proteases induce proinflammatory mediators that augment procoagulant activity and amplify the consumptive process. Endogenous anticoagulant pathways are essential to regulate these proteases and prevent uncontrolled DIC.

Endogenous Anticoagulant Pathways in Disseminated Intravascular Coagulation

The development of DIC is counteracted by several mechanisms. First, coagulation inhibitors regulate the coagulation mechanism. These inhibitors include antithrombin (AT), the proteins C system, and TF pathway inhibitor (TFPI) (Fig. 141-2).[7] AT, which complexes and inhibits thrombin and factor Xa, is one of the most important inhibitors, and reduced AT levels are a characteristic of DIC. Reduction in AT levels reflects a combination of reduced protein synthesis as well as increased clearance through the formation of protease–AT

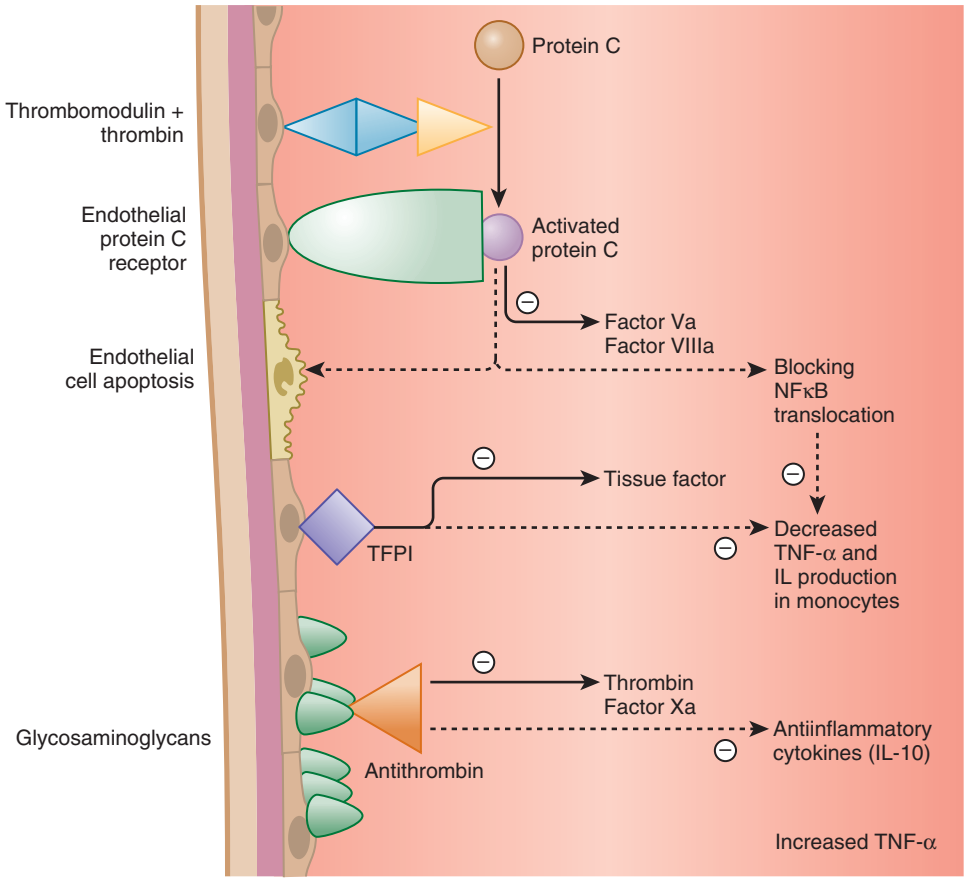

Figure 141-2 PHYSIOLOGICAL ANTICOAGULANT MECHANISMS IN DISSEMINATED INTRAVASCULAR COAGULATION. Physiological anticoagulant mechanisms (activated protein C system, tissue factor pathway inhibitor [TFPI], and antithrombin) are not only involved in blocking thrombin generation and thrombin activity but also affect inflammatory pathways. *IL,* Interleukin; *NFκB,* nuclear factor kappa-B; *TNF,* tumor necrosis factor.

complexes and by degradation by neutrophil elastase. In addition, cytokines may impair proteoglycan synthesis in the vessel wall, thereby reducing the availability of heparin sulphate for potentiation of AT activity.

In animal models of experimental bacteremia, AT concentrate infusion increases survival, reduces the severity of DIC, and lowers the levels of IL-6 and IL-8. Therefore, in addition to its anticoagulant function, AT may also have an antiinflammatory effect.

Activated protein C (APC) and its cofactor protein S form a second line of defense. Thrombin binds to the endothelial cell membrane–associated molecule thrombomodulin, and this complex converts protein C to its active form, APC.[13] In addition, the thrombin–thrombomodulin complex accelerates the conversion of TAFI. APC activates factors Va and VIIIa by proteolytic cleavage, thus slowing down the coagulation cascade. Endothelial cells, primarily of large blood vessels, express an endothelial protein C receptor (EPCR), which augments the activation of protein C at the cell surface. APC has antiinflammatory effects on mononuclear cells and granulocytes, which may be distinct from its anticoagulant activity. Administration of APC prevented thrombin-induced thromboembolism in mice, mainly through its antithrombotic effect. In addition, several studies have demonstrated antiinflammatory effects of APC.

In contrast, defects in the protein C mechanism enhance the vulnerability to inflammatory reactions and DIC. In patient studies, lowered levels of protein C and protein S are associated with increased mortality. Mice with a one allel targeted disruption of the protein C gene, causing heterozygous protein C deficiency, displayed a more severe DIC and associated inflammatory response. Blockade of the activity of protein C by infusion of C4 binding protein turns a sublethal model of *E. coli* in baboons into a lethal model. Blockade of EPCR by a neutralizing monoclonal antibody also increased mortality in the *E. coli* baboon model. Vice versa, infusion of PC in the same model protected against DIC and dying. Thus it appears that the protein C mechanism is of great importance in the host defense against sepsis and DIC. In situations associated with DIC and systemic inflammation, TNF-α and IL-1 may significantly downregulate the cellular expression of thrombomodulin, as suggested by cell culture experiments. However, in vivo studies suggest that EPCR is not downregulated in sepsis but upregulated and that this effect is mediated by thrombin. The formation of thrombin may induce the shedding of EPCR by the endothelium caused by activation of metalloproteinases by thrombin. It is presently unknown whether thrombomodulin is also cleaved by similar mechanisms.

A third inhibitory mechanism constitutes TFPI. This molecule, which exists in several pools either endothelial cell associated or lipoprotein bound in plasma, inhibits the TF–factor VIIa complex by forming a quaternary complex in which factor Xa is the fourth component. Clinical studies in septic patients have not provided clues as to its importance because in the majority of patients, the levels of TFPI are not diminished compared with normal individuals. This may be explained by the lack of downregulatory effects of inflammatory mediators on cultured endothelial cells. The relevance of TFPI in DIC is illustrated by two lines of experimentation. First, depletion of TFPI sensitized rabbits to TF-induced DIC. Second, TFPI infusion protected against the harmful effects of *E. coli* in primates. In this study, TFPI not only blocked DIC, but all baboons challenged with lethal amounts of *E. coli* showed a marked improvement in vital functions and survived the experiment without apparent complications. An experimental study in volunteers confirmed the potential of TFPI to block the procoagulant pathway triggered by endotoxin.

In general, the presence of intact function and normal plasma levels of inhibitors appears to be important in the defense against DIC. It should be noted, however, that there are no strong indications that humans with congenital deficiencies of inhibitors would have a greater chance of developing DIC, but this issue remains to be explored. In addition, the influence of inhibitors in modifying the interaction between coagulation and inflammation deserves further attention.

Fibrinolysis

In experimental models of DIC, fibrinolysis is activated, demonstrated by an initial activation of plasminogen activation, followed by a marked impairment caused by the release in blood of plasminogen activator inhibitor, type 1 (PAI-1). The latter inhibitor strongly inhibits fibrinolysis causing a net procoagulant situation. The molecular basis is cytokine-mediated activation of vascular endothelial cells; TNF-α and Il-1 decreased tissue plasminogen activator (t-PA) and increased PAI-1 production. TNF-α increased urokinase plasminogen activator (u-PA) production in endothelial cells. Endotoxin and TNF-α stimulated PAI-1 production in the livers, kidneys, lungs, and adrenal glands of mice. The net procoagulant state is illustrated by a late rise in fibrin breakdown fragments after *E. coli* challenge of baboons. Experimental data also indicate that the fibrinolytic mechanism is active in clearing fibrin from organs and circulation. Endotoxin-induced fibrin formation in the kidneys and adrenal glands was most dependent on a decrease in u-PA. PAI-1 knock-out mice challenged with endotoxin did not develop thrombi in the kidney in contrast to wild-type (WT) animals. Endotoxin administration to mice with a functionally inactive thrombomodulin gene (TMProArg mutation) and defective protein C activator cofactor function caused fibrin plugs in the pulmonary circulation, but WT animals did not develop macroscopic fibrin. This phenomenon proved to be temporary, with detectable thrombi at 4 hours after endotoxin and disappearance of clots at 24 hours in animals sacrificed at that time point. These experiments demonstrate that fibrinolytic action is required to reduce the extent of intravascular fibrin formation.

Fibrinolytic activity is markedly regulated by PAI-1, the principal inhibitor of this system. Recent studies have shown that a functional mutation in the PAI-1 gene, the 4G/5G polymorphism, not only influenced the plasma levels of PAI-1 but was also linked to clinical outcome of meningococcal septicemia. Patients with the 4G/4G genotype had significantly higher PAI-1 concentrations in plasma and an increased risk of death. Further investigations demonstrated that the PAI-1 polymorphism did not influence the risk of contracting meningitis as such but probably increased the likelihood of developing septic shock from meningococcal infection. These studies are the first evidence that genetically determined differences in the level of fibrinolysis influences the risk of developing complications of a gram-negative infection. In other clinical studies in cohorts of patients with DIC, high plasma levels of PAI-1 were one of the best predictors of mortality. These data suggest that DIC contributes to mortality in this situation, but as indicated earlier, the fact that PAI-1 is an acute phase protein, a higher plasma concentration may also be a marker of disease rather than a causal factor.

CLINICAL MANIFESTATIONS

The clinical manifestation of DIC may vary dependent on the underlying disorder. The extreme end of the spectrum is acute, severe DIC, which often occurs in the setting of sepsis, major trauma, obstetric calamities, and severe immunologic responses. Diffuse multiorgan bleeding, hemorrhagic necrosis, microthrombi in small blood vessels, and thrombi in medium and large blood vessels are common findings at autopsy, although patients who had unequivocal clinical and laboratory signs of DIC may not have confirming postmortem findings. Conversely, some patients in whom clinical and laboratory signs were not consistent with DIC had typical autopsy findings. This occasional lack of correlation among clinical, laboratory, and pathologic findings is partly attributable to extensive postmortem changes in the blood (e.g., excessive fibrinolysis) but remains unexplained in most instances. Organs most frequently involved by diffuse microthrombi are the lungs and kidneys, followed by the brain, heart, liver, spleen, adrenal glands, pancreas, and gut. Specific immunohistologic techniques and ultrastructural analysis have revealed that most thrombi consist of fibrin monomers or polymers in combination with platelets. In addition, involvement of activated mononuclear cells and other signs of

inflammatory activation are frequently present. In cases of long-lasting DIC, organization and endothelialization of the microthrombi are often observed. Acute tubular necrosis is more frequent than renal cortical necrosis. Clinically, thrombotic occlusive events occur first as the result of microthrombi of fibrin or platelets that obstruct the microcirculation of organs. These thrombi result from clots that form either in the circulation or in situ in arterioles, capillaries, or venules. Circulatory obstruction produces organ hypoperfusion and even ischemia, infarction, and necrosis. The process is disseminated throughout the microcirculation; therefore, all organs are potentially vulnerable.

In contrast to acutely ill patients with complicated, severe DIC, other patients may have mild or protracted clinical manifestations of consumption or even subclinical disease manifest by only laboratory abnormalities.[1] The clinical picture of subacute to chronic DIC generally occurs in patients with malignancy, particularly with mucin-producing adenocarcinomas and acute promyelocytic leukemia (APL). The latter usually is dominated by a hemorrhagic presentation, but venous thrombotic manifestations are more common in the former. In addition, patients with solid tumors may develop nonbacterial thrombotic endocarditis with systemic arterial embolization and infarction. Another cause of subacute to chronic DIC is the retained dead fetus syndrome. These patients have an extremely variable presentation from asymptomatic to mild or moderate skin and mucous membrane bleeding.

It is important to stress that DIC is not a disease in itself but is always secondary to an underlying disorder that causes the activation of coagulation. The underlying disorders most commonly known to be associated with DIC are listed in the box on Clinical Conditions That Are Most Frequently Complicated by Disseminated Intravascular Coagulation and are described in detail below.

Clinical Conditions That Are Most Frequently Complicated by Disseminated Intravascular Coagulation

- Sepsis or severe infection
- Trauma, burn, or heatstroke
- Malignancy
 - Solid tumors
 - Acute leukemia
- Obstetric conditions
 - Amniotic fluid embolism
 - Abruptio placentae
 - HELLP syndrome
- Vascular abnormalities
 - Kasabach-Merritt syndrome
 - Other vascular malformations
 - Aortic aneurysms
- Severe allergic or toxic reactions
- Severe immunologic reactions (e.g., transfusion reaction)

Disseminated Intravascular Coagulation in Infectious Disease

Systemic infections are among the most common causes of DIC. Immunocompromised patients, asplenic patients whose ability to clear bacteria (particularly pneumococci) is impaired, and newborns whose anticoagulant systems are immature are particularly prone to infection-induced DIC. Infections may be superimposed on trauma or malignancies, which themselves are potential triggers of DIC. In addition, infections can aggravate bleeding and thrombosis by directly inducing thrombocytopenia, hepatic dysfunction, and shock, which can lead to diminished blood flow in the microcirculation.

Clinically overt DIC occurs in 30% to 50% of patients with gram-negative or -positive sepsis. Extreme examples of sepsis-related DIC are streptococcus A toxic shock syndrome, which is characterized by deep tissue infection, vascular collapse, vascular leakage, and multiple organ dysfunction. M protein released from streptococci forms complexes with fibrinogen that bind to β_2 integrins on neutrophils, leading to their activation and meningococcemia, a fulminant gram-negative infection characterized by extensive hemorrhagic necrosis, DIC, and shock. More frequent gram-negative infections associated with DIC are caused by *Pseudomonas aeruginosa, E. coli,* and *Proteus vulgaris.* Patients with these infections may only have laboratory evidence of activated coagulation or they may present with severe DIC.

Activation of the coagulation system has also been documented with nonbacterial pathogens, such as viruses, protozoa (malaria), and fungi.[14] Common viral infections, such as influenza, varicella, rubella, and rubeola, are rarely associated with DIC. Some viral infections can cause "hemorrhagic fevers" characterized by fever, hypotension, bleeding, and renal failure. Laboratory evidence of DIC can accompany Korean, rift valley, and dengue-related hemorrhagic fevers. Protozoan infections, such as cerebral malaria, may be associated with overt DIC. In these cases, secondary deficiency of a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13 (ADAMTS13), the von Willebrand cleaving protease, may occur. Such deficiency may also complicate other types of sepsis-induced DIC and may enhance platelet–vessel wall interactions, thereby contributing to thrombosis in the microcirculation.[15]

An extreme form of DIC is represented by purpura fulminans, a severe, often lethal form of DIC in which extensive areas of the skin over the extremities and buttocks undergo hemorrhagic necrosis. The disease predominantly affects infants and children and is rare in adults. Diffuse microthrombi in small blood vessels leads to necrosis and vasculitis may also be found in biopsies of skin lesions. The disorder can occur 2 to 4 weeks after mild infection, such as scarlet fever, varicella, or rubella, or can occur during an acute viral or bacterial infection in patients with acquired or hereditary deficiencies of protein C or protein S. The syndrome mimics neonatal homozygous protein C or protein S deficiency, in which purpura fulminans, with or without extensive thrombosis, develops soon after birth.

Disseminated Intravascular Coagulation in Trauma, Brain Injury, Burns, and Heatstroke

The time interval between trauma and medical intervention correlates with the development and magnitude of DIC. Experience during wars proved that fast evacuation and prompt medical care reduce the risk of DIC. Extensive exposure of TF to the blood circulation and hemorrhagic shock probably are the most immediate triggers of DIC in such instances, although direct proof of this mechanism is lacking. An alternative hypothesis is that cytokines play a pivotal role in the occurrence of DIC in trauma patients. In fact, the changes in cytokine levels are virtually identical in trauma patients and septic patients.[16] The levels of TNF-α, IL-1β, PAI-1, circulating TF, plasma elastase derived from neutrophils, and soluble thrombomodulin all can be elevated in patients with signs of DIC, predicting multiple organ dysfunction (MOD) (ARDS included) and death. Careful monitoring of laboratory signs of DIC, reduced fibrinolytic activity, and perhaps low AT levels also are useful for predicting the outcome of such patients.

In adults and children with head injuries, a high rate of mortality occurred when DIC was present. A laboratory DIC score has predictive value for prognosis in patients with head injuries, thereby supplementing the Glasgow Coma Scale score. Brain injury can be associated with DIC, most likely because the injury exposes the abundant TF of the brain to blood. Specimens of contused brain, obtained during surgery in patients with head injury and of liver, lungs, kidneys, and pancreas obtained during autopsy, revealed microthrombi in arterioles and venules.

Bleeding, laboratory tests indicative of DIC, and vascular microthrombi in biopsies of undamaged skin have been described in patients with extensive burns. Kinetic studies with labeled fibrinogen and labeled platelets disclosed that in addition to systemic consumption of hemostatic factors, significant local consumption occurs in

burned areas. TF exposed to blood at sites of burned tissue, the systemic inflammatory response syndrome induced by the burn, and the common presence of superimposed infections all can trigger DIC. Local activation of coagulation in the bronchoalveolar compartment may contribute to acute lung injury in these patients.

Severe hemorrhagic diathesis and multiple organ failure, indicative of DIC, may accompany heatstroke.[17] Diffuse fibrin deposition and hemorrhagic infarctions are found in fatal human cases. DIC associated with profound fibrin(ogen)olysis is evident in patients with heatstroke. The possible triggers of DIC in patients with heatstroke include endothelial cell damage and TF released from heat-damaged tissues. In a series of 18 critically ill patients from Paris with heatstroke during the 2003 heat wave in Western Europe that caused numerous deaths in France,[17] patients had very high levels of IL-6 and IL-8. In addition, there was a striking activation of white blood cells, as demonstrated by β2-integrin upregulation and increased production of reactive oxygen species. All patients also had evidence of a significant systemic activation of coagulation, and DIC was present in about 35% of patients. There was a marked correlation between the extent of inflammation and coagulation activation and the clinical severity of the heatstroke.

Disseminated Intravascular Coagulation in Obstetric Complications

Placental abruption is a leading cause of perinatal death.[18] Older multiparous women or patients with one of the hypertensive disorders of pregnancy are thought to be at highest risk. The severe hemostatic failure accompanying abruptio placentae is the result of acute DIC emanating from the introduction of large amounts of TF into the blood circulation from the damaged placenta and uterus. Amniotic fluid has been shown to be able to activate coagulation in vitro, and the degree of placental separation correlates with the extent of DIC, suggesting that leakage of thromboplastin-like material from the placental system is responsible for the occurrence of DIC. Abruptio placentae occurs in 0.2% to 0.4% of pregnancies, but only 10% of these cases are associated with DIC. Different grades of severity are found among those who develop DIC, with only the more severe forms resulting in shock and fetal death.

Amniotic fluid embolism is a rare but serious complication of pregnancy and delivery. A maternal mortality rate of 86% was reported in a 1979 review of 272 cases, but in a more recent population-based study, the maternal mortality rate (26.4%) was significantly lower. Patients predisposed to amniotic fluid embolism are multiparous women whose pregnancies are postmature with large fetuses and women undergoing a tumultuous labor after pharmacologic or surgical induction. Apparently, amniotic fluid is introduced into the maternal circulation through tears in the chorioamniotic membranes, rupture of the uterus, and injury of uterine veins. The trigger of DIC probably is TF present in amniotic fluid. The mechanical obstruction of pulmonary blood vessels by fetal debris, meconium, and other particulate matter in the amniotic fluid enhances local fibrin–platelet thrombus formation and fibrinolysis. The extensive occlusion of the pulmonary arteries and an acute anaphylactoid response reminiscent of severe systemic inflammatory response syndrome provoke sudden dyspnea, cyanosis, acute cor pulmonale, left ventricular dysfunction, shock, and convulsions. These symptoms are followed within minutes to several hours by severe bleeding in 37% of patients. Hemorrhage is particularly severe from the atonic uterus, puncture sites, gastrointestinal tract, and other organs.

Some studies provided evidence for significant activation of coagulation, in its most extreme form DIC, in preeclampsia and eclampsia. In a large series of patients, a good correlation was noted between the clinical severity and abnormalities in platelet counts and fibrin(ogen) degradation products. Also consistent with DIC were results of assays of sensitive parameters of thrombin generation and activation of fibrinolysis, such as thrombin-antithrombin (TAT) complexes, D-dimer, and fibrinopeptide Bβ1-42. Despite these observations, administration of heparin to patients with preeclampsia and eclampsia has not resulted in convincing benefits. The syndrome of hemolysis (H), elevated liver enzymes (EL), low platelet count (LP), and severe epigastric pain is another complication of pregnancy-induced hypertension. Liver biopsy findings of fibrin deposition in hepatic blood vessels and laboratory tests consistent with DIC in a significant proportion of patients imply that DIC plays a role in the pathogenesis of the syndrome. However, according to current insights, thrombotic microangiopathy rather than DIC causes the coagulation abnormalities seen in patients with hypertensive disorders of pregnancy.

Disseminated Intravascular Coagulation in Malignancy

Patients with solid tumors are vulnerable to risk factors and additional triggers of DIC that can aggravate thromboembolism and bleeding.[19] Risk factors include advanced age, stage of the disease, and use of chemotherapy or antiestrogen therapy. Triggers include septicemia, immobilization, and involvement of the liver by metastases that impede the function of the liver in controlling DIC. Microangiopathic hemolytic anemia frequently is induced by DIC in patients with malignancies and is particularly severe in patients with widespread intravascular metastases of mucin-secreting adenocarcinomas. Solid tumor cells can express different procoagulant molecules, including TF, which forms a complex with factor VII(a) to activate factors IX and X, and a cancer procoagulant (CP), a cysteine protease with factor X activating properties. In breast cancer, TF is expressed by vascular endothelial cells as well as the tumor cells. TF also appears to be involved in tumor metastasis and angiogenesis. Cancer procoagulant is an endopeptidase that can be found in extracts of neoplastic cells but also in the plasma of patients with solid tumors. The exact role of CP in the pathogenesis of cancer-related DIC is unclear. Interactions of P- and L-selectins with mucin from mucinous adenocarcinoma can induce formation of platelet microthrombi and probably constitute one-third mechanism of cancer-related thrombosis. Depending on the rate and quantity of exposure or influx of shed vesicles from tumors containing TF, a nonovert or overt DIC develops.

Numerous reports on DIC and fibrinolysis complicating the course of acute leukemias have been published. In 161 consecutive patients presenting with acute myeloid leukemia, DIC was diagnosed in 52 (32%). In acute lymphoblastic leukemia, DIC was diagnosed in 15% to 20%.[20] Some reports indicate that the incidence of DIC in acute leukemia patients might further increase during remission induction with chemotherapy. In patients with acute APL, DIC is present in more than 90% of patients at the time of diagnosis or after initiation of remission induction. The pathogenesis of hemostatic disturbance in APL is related to properties of the malignant cells and their interaction with the host's endothelial cells. APL cells express TF and the cancer procoagulant that can initiate coagulation, and they release IL-Iβ and TNF-α, which downregulate endothelial thrombomodulin, thereby compromising the protein C anticoagulant pathway. APL cells also express increased amounts of annexin II, which mediates augmented conversion of plasminogen to plasmin. The overall results of these processes are DIC and hyperfibrinolysis, ensued by major bleeding that can lead to death. All-*trans*-retinoic acid, used for induction and maintenance therapy of APL, inhibits in vitro and in vivo the deleterious effect of APL cells and has led to a reduced frequency of early hemorrhagic death.

Disseminated Intravascular Coagulation With Vascular Disorders

Rarely, vascular anomalies can trigger DIC. With some large aortic aneurysms, localized consumption of platelets and fibrinogen can produce coagulation abnormalities and bleeding.[21] In a series of patients with aortic aneurysms, 40% had elevated levels of fibrin(ogen) degradation products, but only 4% had laboratory evidence of DIC or bleeding.[21] Factors that predispose such patients to the development of DIC include a large aneurysm, dissection, and expansion.

Coagulation in these cases likely is triggered by the abundant TF in atherosclerotic plaques. Localized pain may occur, likely from thrombosis of vascular channels within the hemangiomas, and there may be bleeding after trauma or surgery because of the consumptive process. Increased fibrinogen consumption reflects hypofibrinolysis, which may be driven by t-PA release from the abnormal endothelium lining the tumor walls. Patients with this syndrome exhibit accelerated platelet turnover and accumulation of labeled platelets and fibrinogen in the hemangiomas.

Kasabach and Merritt were the first to describe bleeding in association with giant cavernous hemangiomas, benign tumors found in newborns or children that can evolve into convoluted masses of abnormal vascular channels that sequester and consume platelets and fibrinogen. Hemangiomas may regress spontaneously, and some respond to radiation or laser therapy.

Disseminated Intravascular Coagulation With Liver Disease

The levels of most coagulation factors, endogenous anticoagulants, and major components of the fibrinolytic system are reduced in patients with severe liver disease, reflecting reduced synthesis. In addition, the capacity of the liver to clear factors IXa, Xa, and XIa and t-PA is decreased. Thrombocytopenia is common because of hypersplenism and decreased hepatic production of thrombopoietin. The similarities between the hemostatic defects with liver disease and those with DIC have evoked controversy as to the contribution of DIC to the coagulopathy of liver disease. Several laboratory and clinical observations support the concept that DIC accompanies hepatic disorders. They include a reduced half-life of radiolabeled fibrinogen that is reversed by heparin administration, failure of replacement therapy to significantly increase the levels of hemostatic factors (suggesting ongoing consumption), and increased levels of markers of activation of coagulation. All of these findings are consistent with increased thrombin generation. Against the DIC hypothesis are the observation that microthrombi are found in only 2% of the tissues from patients who die of liver disease and the fact that the increased fibrinogen turnover can be explained by extravascular accumulation. Current thinking is that DIC is rare in patients with liver disease, but such patients are sensitive to the triggers of DIC because of the decreased synthetic capacity of the diseased liver and its inability to clear activated clotting factors. In patients who undergo peritoneovenous shunting for severe ascites, those with underlying liver disease are more likely to develop DIC than those who have normal livers.

Disseminated Intravascular Coagulation With Toxic Reactions or Snake Bites

The venom of certain snakes, particularly vipers and rattlesnakes, can produce a coagulopathy similar to that of DIC.[22] Prominent among these species are the *Vipera, Echis (Echis carinatus* or *Echis coloratus), Aspis, Crotalus, Bothrops,* and *Agkistrodon* spp. Venoms of these snakes contain enzymes or peptides that (1) release fibrinopeptide A *(Agkistrodon rhodostoma);* (2) activate prothrombin even in the absence of calcium *(E. carinatus);* (3) activate factors X and V (Russell viper venom); (4) degrade fibrinogen *(Agkistrodon acutus);* (5) induce platelet aggregation; (6) inhibit platelet aggregation because of the presence of arginine-glycine-aspartic acid–containing peptides; (7) activate protein C; and (8) damage endothelial cells, which leads to bleeding, tissue ischemia, and edema. Interestingly, victims of snake bites rarely have excessive bleeding or thromboembolism despite the abnormal coagulation tests and DIC-like picture.

LABORATORY MANIFESTATIONS

Thrombocytopenia or a rapidly declining platelet count is an important diagnostic hallmark of DIC. However, only 35% to 44% of critically ill patients develop thrombocytopenia (platelet count <150 $\times 10^9$/L). Consequently, the specificity of thrombocytopenia for the diagnosis of DIC is limited.[10] A platelet count of less than 100 $\times 10^9$/L is seen in 50% to 60% of DIC patients, and 10% to 15% of patients have a platelet count below 50×10^9/L. In surgical or trauma patients with DIC, more than 80% of patients have platelet counts less than 100×10^9/L.

Consumption of coagulation factors leads to low levels of coagulation factors in patients with DIC. In addition, impaired synthesis—for example, caused by impaired liver function or a vitamin K deficiency—and loss of coagulation proteins because of massive bleeding may play a role in DIC as well. Although the accuracy of the measurement of one-stage clotting assays in DIC has been contested (because of the presence of activated coagulation factors in plasma), the level of coagulation factors appears to correlate well with the severity of the DIC. The low level of coagulation factors is reflected by prolonged coagulation screening tests, such as the PT or the aPTT. A prolonged PT or aPTT occurs in 14% to 28% of intensive care patients but is present in more than 95% of patients with DIC.

Plasma levels of factor VIII are paradoxically increased in most patients with DIC, probably because of massive release of von Willebrand factor from the endothelium in combination with acute phase behavior of factor VIII. Recent studies have pointed to a relative insufficiency of the von Willebrand cleaving protease ADAMTS13, thereby causing high concentrations of ultra-large von Willebrand multimers in plasma, which may facilitate platelet–vessel wall interaction and the subsequent development of thrombotic microangiopathy, which may contribute to organ dysfunction.[15]

Measurement of fibrinogen has been widely advocated as a useful tool for the diagnosis of DIC but in fact is not very helpful to diagnose DIC in most cases.[23] Fibrinogen acts as an acute-phase reactant and despite ongoing consumption plasma levels can remain well within the normal range for a long period of time. In a consecutive series of patients, the sensitivity of a low fibrinogen level for the diagnosis of DIC was only 28%, and hypofibrinogenemia was detected in very severe cases of DIC only.

Markers of Fibrin Generation and Degradation

Plasma levels of fibrin split products are frequently used for the diagnosis of DIC.[24] Fibrin split products are detectable in 42% of a consecutive series of intensive care patients, in 80% of trauma patients, and in 99% of patients with sepsis and DIC. Fibrin degradation products (FDPs) may be detected by specific enzyme-linked immunosorbent assays (ELISAs) or by latex agglutination assays, allowing rapid and bedside determination in emergency cases. None of the available assays for FDPs discriminates between degradation products of cross-linked fibrin and fibrinogen degradation, which may cause spuriously high results. The specificity of high levels of fibrin degradation products is therefore limited, and many other conditions, such as trauma, recent surgery, inflammation, or venous thromboembolism, are associated with elevated FDPs. Because FDPs are metabolized by the liver and secreted by the kidneys, FDP levels are influenced by liver and kidney function. Other tests are specifically aimed at the detection of neoantigens on degraded cross-linked fibrin. One of such tests detects an epitope related to plasmin-degraded cross-linked chain, resulting in fragment D-dimer. These tests better differentiate degradation of cross-linked fibrin from fibrinogen or FDPs. D-dimer levels are high in patients with DIC but also poorly distinguish patients with DIC from patients with venous thromboembolism, recent surgery, or inflammatory conditions. Theoretically, measurement of soluble fibrin or fibrin monomers in plasma could be helpful to diagnose intravascular fibrin formation in DIC. Indeed, initial clinical studies indicate that if the concentration of soluble fibrin has increased above a defined threshold, a diagnosis of DIC can be made. The only problem so far is that a reliable test is not available for quantitating soluble fibrin in plasma. Because soluble fibrin in plasma can only be generated

intravascularly, this test will not be influenced by extravascular fibrin formation, which, for example, may occur during local inflammation or trauma.

Endogenous Coagulation Inhibitors

Plasma levels of physiological coagulation inhibitors, such as protein C and AT, may be useful indicators of ongoing coagulation activation.[24] Low levels of these coagulation inhibitors are found in 40% to 60% of critically ill patients and in 90% of DIC patients.

Levels of protein C may indicate the severity of the DIC. In patients with meningococcal septicemia, very low plasma levels of protein C are observed, and this may play a pivotal role in the occurrence of purpura fulminans in these patients. In fact, the plasma level of protein C may also be regarded as a strong predictor for the outcome in DIC patients. Observations in patients with severe gram-negative septicemia indeed confirmed the downregulation of thrombomodulin in vivo and impaired activation of protein C. Low levels of free protein S (the cofactor of APC) may further compromise an adequate function of the protein C system.

Antithrombin is the principal inhibitor of thrombin and may be readily exhausted during continuous thrombin generation. Plasma levels of AT have been shown to be potent predictors for survival in patients with sepsis and DIC. During severe inflammatory responses, AT levels are markedly decreased not only because of consumption but also because of impaired synthesis (as a result of a negative acute phase response) and degradation by elastase from activated neutrophils.

Fibrinolytic Markers

Fibrinolytic activation in DIC may be monitored by measurement of plasma levels of plasminogen and α2-antiplasmin. Low levels may indicate consumption of these proteins. Because of the relatively low plasma concentration of α_2-antiplasmin, the determination of this protease inhibitor is a helpful test for judging the dynamics of fibrinolysis. Plasmin generation may be best judged by measurement of plasmin-α2-antiplasmin (PAP) complexes, which are indeed moderately elevated in patients with DIC. However, because the concentration of α2-antiplasmin is relatively low and therefore sensitive to relatively rapid exhaustion, this test may underestimate total fibrinolytic activity. At low concentrations of α2-antiplasmin, other protease inhibitors, such as AT, α2-macroglobulin, α1-antitrypsin, and C1-inhibitor, may act as plasmin inhibitors as well. The apparent insufficient fibrinolytic activity in patients with DIC is attributed to high levels of the inhibitor of plasminogen activation, PAI-1. Indeed, plasma levels of PAI-1 are elevated in patients with DIC and various underlying conditions and are strongly correlated with an unfavorable outcome. Of interest, studies have shown that a functional mutation in the PAI-1 gene, the 4G/5G polymorphism, not only influenced the plasma levels of PAI-1 but was also linked to clinical outcome of meningococcal septicemia and associated DIC. Patients with the 4G/4G genotype had significantly higher PAI-1 concentrations in plasma and an increased risk of death.

Point-of-Care Tests

Thrombelastography (TEG), a method that was developed decades ago, provides an overall picture of ex vivo coagulation. Modern techniques, such as rotational thrombelastography (ROTEM), enable bedside performance of this test and have again become popular in acute care settings.[25] The theoretical advantage of TEG over conventional coagulation assays is that it provides an index of platelet function as well as fibrinolytic activity. Hyper- and hypocoagulability as demonstrated with TEG was shown to correlate with clinically relevant morbidity and mortality in several studies, although its superiority over conventional tests has not unequivocally been established. Also, TEG seems to be overly sensitive to some interventions in the coagulation system, such as administration of fibrinogen, of which the therapeutic benefit remains to be established. There are no systematic studies on the diagnostic accuracy of TEG for the diagnosis of DIC, but the test may be useful for assessing the global status of the coagulation system in critically ill patients.

A new method that has proved sensitive and specific for hypercoagulability in critically ill patients is the activated partial thromboplastin time (aPTT) biphasic waveform analysis. This test, which requires specific instrumentation, detects the presence of precipitates of a complex of very-low-density lipoprotein and C-reactive protein that appears very early in DIC. When such complexes first appear in the plasma of individuals with diseases known to predispose to hypercoagulability, they confer a greater than 90% sensitivity and specificity for subsequent development of DIC and fatal outcome.

Diagnostic Algorithm for Disseminated Intravascular Coagulation

For the diagnosis of overt DIC, a simple scoring system has been developed by the subcommittee on DIC of the ISTH (see box on Diagnostic Algorithm for the Diagnosis of Overt Disseminated Intravascular Coagulation).[5] The score can be calculated based on routinely available laboratory tests, that is, platelet count, PT, a fibrin-related marker (usually D-dimer), and fibrinogen. Tentatively, a score of 5 or more is compatible with DIC, and a score of less than 5 may be indicative but is *not* affirmative for non-overt DIC. For non-overt DIC, more refined scoring systems have been developed, which are currently being evaluated. A recent study showed that the international normalized ratio (INR) can be used (instead of PT prolongation), further facilitating international exchange and standardization. By using receiver-operating characteristics curves, an optimal cutoff for a quantitative D-dimer assay was determined, thereby optimizing sensitivity and the negative predictive value of the system. Prospective studies show that the sensitivity of the DIC score is 93% and the specificity is 98%. Studies in series of patients with specific underlying disorders causing DIC (e.g., cancer, obstetric complications) show similar results. The severity of DIC according to this scoring system is related to the mortality in patients with

Diagnostic Algorithm for the Diagnosis of Overt Disseminated Intravascular Coagulation*

1. Presence of an underlying disorder known to be associated with DIC (see box on Clinical Conditions That Are Most Frequently Complicated by Disseminated Intravascular Coagulation)
 (no = 0; yes = 2)
2. Score global coagulation test results:
 - Platelet count (>100 = 0; <100 = 1; <50 = 2)
 - Level of fibrin markers (e.g., D-dimer, fibrin degradation products)
 (no increase: 0; moderate increase: 2; strong increase: 3)†
 - Prolonged prothrombin time
 (<3 sec = 0; >3 sec but <6 sec = 1; >6 sec = 2)
 - Fibrinogen level
 (>1.0 g/L = 0; <1.0 g/L = 1)
3. Calculate score
4. If >5: compatible with overt DIC; repeat scoring daily
 If <5: suggestive (not affirmative) for non-overt DIC; repeat in the next 1 or 2 days

*According to the Scientific Standardization Committee of the International Society of Thrombosis and Haemostasis.[5]
†Strong increase greater than five times the upper limit of normal; moderate increase is greater than upper limit of normal but less than five times the upper limit of normal

sepsis.[9] Linking prognostic determinants from critical care measurement scores such as APACHE-II to DIC scores is an important means to assess prognosis in critically ill patients. Similar scoring systems have been developed and extensively evaluated in Japan. The major difference between the international and Japanese scoring systems seems to be a slightly higher sensitivity of the Japanese algorithm, although this may be attributable to different patient populations because Japanese series typically include relatively large numbers of patients with hematologic malignancies.

DIFFERENTIAL DIAGNOSIS

There are several other causes of coagulation abnormalities in patients with underlying disorders known to be associated with DIC. A complicating factor is that more than one diagnosis for the coagulopathy may be present in one patient; for example, a septic patient with DIC may have liver failure and a vitamin K deficiency as well.

The differential diagnosis of thrombocytopenia in patients with suspected DIC is shown in Table 141-1. Sepsis itself is a clear risk factor for thrombocytopenia in critically ill patients, and the severity of sepsis correlates with the decrease in platelet count. The principal factors that contribute to thrombocytopenia in patients with sepsis are impaired platelet production, increased consumption or destruction, or sequestration platelets in the spleen or along the endothelial surface. Impaired production of platelets from within the bone marrow may seem contradictory to the high levels of platelet production-stimulating proinflammatory cytokines, such as TNF-α and IL-6, and high concentration of circulating thrombopoietin in patients with sepsis. These cytokines and growth factors should theoretically stimulate megakaryopoiesis in the bone marrow. However, in a substantial number of patients with sepsis, marked hemophagocytosis may occur. This pathologic process consists of active phagocytosis of megakaryocytes and other hematopoietic cells by monocytes and macrophages, hypothetically because of stimulation with high levels of macrophage colony-stimulating factor (M-CSF) in sepsis.

Table 141-1 Differential Diagnosis of Thrombocytopenia in Suspected Disseminated Intravascular Coagulation

Differential Diagnosis	Additional Diagnostic Clues
DIC	Prolonged aPTT and PT, increased FDP, low levels of AT or protein C
Sepsis without DIC	Positive (blood) cultures, positive sepsis criteria, hematophagocytosis in BM aspirate
Massive blood loss	Major bleeding, low hemoglobin, prolonged aPTT and PT
Thrombotic microangiopathy	Schistocytes in blood smear, Coombs-negative hemolysis, fever, neurologic symptoms, renal insufficiency, coagulation test results usually normal, ADAMTS13 levels decreased
Heparin-induced thrombocytopenia	Use of heparin, venous or arterial thrombosis, positive HIT test (usually immunoassay for heparin-platelet factor 4 antibodies), increase in platelet count after cessation of heparin; coagulation tests usually normal
Immune thrombocytopenia	Antiplatelet antibodies, normal or increased number of megakaryocytes in BM aspirate, TPO decreased; coagulation tests usually normal
Drug-induced thrombocytopenia	Decreased number of megakaryocytes in BM aspirate or detection of drug-induced antiplatelet antibodies, increase in platelet count after cessation of drug; coagulation test results usually normal

ADAMTS13, A disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13; *aPTT,* activated partial thromboplastin time; *AT,* antithrombin; *BM,* bone marrow; *DIC,* disseminated intravascular coagulation; *FDP,* fibrin degradation product; *HIT,* heparin-induced thrombocytopenia; *PT,* prothrombin time; TPO, thrombopoietin.

Heparin-induced thrombocytopenia (HIT) is caused by a heparin-induced antibody that binds to the heparin–platelet factor IV complex on the platelet surface. This may result in massive platelet activation and as a consequence a consumptive thrombocytopenia and arterial and venous thrombosis occur. A consecutive series of critically ill patients who received heparin revealed an incidence of 1% in this setting. Unfractionated heparin (UFH) carries a higher risk of HIT than low-molecular-weight (LMW) heparin. Thrombosis may occur in 25% to 50% of patients with HIT (with fatal thrombosis in 4%-5%). The diagnosis of HIT is based on the detection of HIT antibodies in combination with the occurrence of thrombocytopenia in a patient receiving heparin with or without concomitant arterial or venous thrombosis. It should be mentioned that the commonly used ELISA for HIT antibodies has a high negative predictive value (100%) but a very low positive predictive value (10%).The gold standard for the diagnosis of HIT is a sensitive platelet activation assay; however, this test is usually not routinely available. Normalization in the number of platelets in 1 to 3 days after discontinuation of heparin may further support the diagnosis of HIT.

The group of thrombotic microangiopathies encompasses syndromes such as thrombotic thrombocytopenic purpura, hemolytic uremic syndrome, severe malignant hypertension, chemotherapy-induced microangiopathic hemolytic anemia, and the HELLP (hemolysis, elevated liver enzymes, low platelet count) syndrome. A common pathogenetic feature of these clinical entities appears to be endothelial damage, causing platelet adhesion and aggregation, thrombin formation, and an impaired fibrinolysis. The multiple clinical consequences of this extensive endothelial dysfunction include thrombocytopenia; mechanical fragmentation of red blood cells with hemolytic anemia; and obstruction of the microvasculature of various organs, such as the kidneys and brain (leading to renal failure and neurologic dysfunction, respectively). Despite this common final pathway, the various thrombotic microangiopathies have different underlying etiologies.

Drug-induced thrombocytopenia is another frequent cause of thrombocytopenia in critically ill patients. Thrombocytopenia may be caused by drug-induced myelosuppression, by cytostatic agents, or by immune-mediated mechanisms. Drug-induced thrombocytopenia is a difficult diagnosis in patients suspected of DIC because these patients are often exposed to multiple agents and have numerous other potential reasons for platelet depletion. Drug-induced thrombocytopenia is often diagnosed based on the timing of initiation of a new agent in relationship to the development of thrombocytopenia after exclusion of other causes of thrombocytopenia. The observation of rapid restoration of the platelet count after discontinuation of the suspected agent is highly suggestive of drug-induced thrombocytopenia.

A prolongation of global coagulation tests may be caused by a deficiency of one or more coagulation factors (Table 141-2). In addition, but more rarely, the presence of an inhibiting antibody, which can have major in vivo relevance (e.g., in acquired hemophilia) but can also be a clinically insignificant laboratory phenomenon, should be considered. The presence of lupus anticoagulants may cause a prolongation of the aPTT and can be associated with thrombocytopenia as well. Paradoxically, lupus anticoagulants may dramatically increase the risk of thrombosis. The presence of an inhibiting antibody can be confirmed by a simple mixing experiment. As a general rule, if a prolongation of a global coagulation test cannot be corrected by mixing 50% of patient plasma with 50% of normal plasma, then an inhibiting antibody is likely to be present.

In general, acquired deficiencies in coagulation factors may be caused by impaired synthesis, massive loss, or increased turnover (consumption). Impaired synthesis is often caused by liver insufficiency or vitamin K deficiency. Vitamin K deficiency may be caused

by poor nutrition in combination with the use of antibiotics that affect intestinal flora and thereby bacterial vitamin K production. The PT is most sensitive to both conditions because this test is highly dependent on the plasma levels of factor VII (a vitamin K–dependent coagulation factor with a shortest half-life of the clotting factors). Liver failure may be differentiated from vitamin K deficiency by measuring factor V, which is not vitamin K dependent. In fact, factor V plays an important role in various scoring systems for severe acute liver failure. Uncompensated loss of coagulation factors may occur after massive bleeding, such as in trauma patients and patients undergoing major surgical procedures. This is particularly common in patients with major blood loss in whom intravascular volume is rapidly replaced with crystalloids, colloids, and red blood cells without simultaneous administration of coagulation factors. This resulting depletional form of coagulopathy may persist and exacerbate the bleeding. In addition, transfusion in these patients may lead to systemic activation of inflammatory processes and may contribute to further coagulation derangements. In hypothermic patients (e.g., trauma patients), measurement of the global coagulation tests may underestimate coagulation in vivo because in the laboratory test tube assays are standardized and performed at 37°C to mimic normal body temperature.

Table 141-2 Differential Diagnosis of Prolonged Activated Partial Thromboplastin Time or Prothrombin Time in Suspected Disseminated Intravascular Coagulation

Test Result	Cause
PT prolonged; aPTT normal	Factor VII deficiency Mild vitamin K deficiency Mild liver insufficiency Low doses of vitamin K antagonists
PT normal; aPTT prolonged	Factor VIII, IX, or XI deficiency UFH Inhibitory antibody or antiphospholipid antibody Factor XII or prekallikrein deficiency
both PT and aPTT prolonged	Factor X, V, or II or fibrinogen deficiency Severe vitamin K deficiency Vitamin K antagonists Global clotting factor deficiency Decreased synthesis: liver failure Increased loss: massive bleeding, DIC

aPTT, Activated partial thromboplastin time; *DIC,* disseminated intravascular coagulation; *PT,* prothrombin time; *UFH,* unfractionated heparin.

THERAPY

Adequate management of patients with DIC depends on vigorous treatment of the underlying disorder to alleviate or remove the inciting injurious cause. For sepsis-induced DIC, treatment includes aggressive use of intravenous organism-directed antibiotics and source control (e.g., by surgery or drainage). Other examples of vigorous treatment of underlying conditions are cancer surgery or chemotherapy, uterus evacuation in patients with abruptio placentae, resection of aortic aneurysm, and debridement of crushed tissue in case of trauma. In addition, intensive support of vital function supportive treatment aimed at the coagulopathy may be helpful (see box on Mainstays of Supportive Treatment of Disseminated Intravascular Coagulation),[6] as outlined in the following.

Platelet and Plasma Transfusion

Low levels of platelets and coagulation factors may increase the risk of bleeding. However, plasma or platelet substitution therapy should not be instituted on the basis of laboratory results alone; it is indicated only in patients with active bleeding and in those requiring an invasive procedure or in those at risk for bleeding complications.[6] The presumed efficacy of treatment with plasma, fibrinogen concentrate, cryoprecipitate, or platelets is not based on randomized controlled trials but appears to be rational therapy in bleeding patients or in patients at risk of bleeding who have a significant depletion of these hemostatic factors. The suggestion that administration of blood components might "add fuel to the fire" has never been proven in clinical or experimental studies.

Replacement therapy for thrombocytopenia should consist of 5 to 10 U of platelet concentrate to raise the platelet count to 20 to 30 $\times 10^9$/L and, in cases in patients who need an invasive procedure, to 50×10^9/L.

One of the major challenges of infusion of fresh-frozen plasma (FFP) in DIC and bleeding is the propensity of the added volume, which is necessary to correct the coagulation defect, to exacerbate capillary leak. This situation can increase the risk of inducing or worsening pulmonary edema and, by extension, predisposes to acute respiratory distress syndrome and induces ascites. Coagulation factor

Mainstays of Supportive Treatment of Disseminated Intravascular Coagulation

Modality	*Details*	*Expectations/Rationale*
Treating the underlying disorder	Dependent on the primary diagnosis	Inhibit or block the complicating pathologic mechanism of DIC in parallel with the response (if any) of the disorder
Antithrombotic agents	Prophylactic heparin to prevent venous thromboembolic complications	Risk of thromboembolism is increased in critically ill patients, trauma patients, and patients with cancer
	(Low-dose) therapeutic heparin in case of confirmed thromboembolism or if clinical picture is dominated by (micro)vascular thrombosis and associated organ failure	Prevent fibrin formation; tip the balance within the microcirculation toward anticoagulant mechanisms and physiologic fibrinolysis; allow reperfusion of the skin, kidneys, and brain
Transfusion	Infuse platelets, plasma and fibrinogen (cryoprecipitate) if there is overt bleeding or a high risk of bleeding	Bleeding should diminish and stop over the course of hours
		Platelet count, coagulation test results, and fibrinogen should return toward normal
Anticoagulant factor concentrates	Recombinant human activated protein C may be effective in sepsis and DIC (24 μg/kg/hr for 4 days)	Restore anticoagulation in microvascular environment and may have antiinflammatory activity
Fibrinolytic inhibitors	Tranexamic acid (e.g., 500-1000 mg every 8-12 hr or ε-aminocaproic acid 1000-2000 mg every 8-12 hr)	May be useful if there is (hyper)fibrinolysis
		Bleeding ceases, but there is a risk of microvascular thrombosis and renal failure

concentrates, such as prothrombin complex concentrate, may partially overcome this obstacle but do not contain essential factors, such as factor V. Moreover, caution is advocated with the use of prothrombin complex concentrates in DIC because it may worsen the coagulopathy because of traces of activated factors that are present in these concentrates. Specific deficiencies of coagulation factors, such as fibrinogen, may be corrected by administration of purified coagulation factor concentrates.

Cryoprecipitate (if available) can be used to rapidly raise the fibrinogen and von Willebrand or factor VIII levels, particularly when bleeding is part of the DIC and fibrinogen level is less than 1 g/L. Cryoprecipitate has at least four to five times the mass of fibrinogen per milliliter of infusate compared with FFP. FFP contains fibrinogen in sufficient amounts for treatment of patients with mild to moderate hypofibrinogenemia.

Anticoagulant Treatment

Heparin therapy in patients with DIC remains controversial. Experimental studies have shown that heparin can at least partly inhibit the activation of coagulation in DIC. However, a beneficial effect of heparin on clinically important outcome events in patients with DIC has not been demonstrated in controlled clinical trials. Also, the safety of heparin treatment is debatable in DIC patients who are prone to bleeding. A large trial in patients with severe sepsis showed a slight but nonsignificant benefit of low-dose heparin on 28-day mortality in patients with severe sepsis and no major safety concerns.[26]

There is general consensus that administration of heparin is beneficial in some categories of DIC, such as metastatic carcinomas, purpura fulminans, and aortic aneurysm (before resection). Heparin also is indicated for treating thromboembolic complications in large vessels and before surgery in patients with chronic DIC. Heparin administration may be helpful in patients with acute DIC when intensive blood component replacement fails to improve excessive bleeding or when thrombosis threatens to cause irreversible tissue injury (e.g., acute cortical necrosis of the kidney or digital gangrene).

Heparin should be used cautiously in all these conditions. In patients with chronic DIC because of metastatic carcinoma or aortic aneurysm, continuous infusion of UFH 500 to 750 U/hr without a bolus injection has been advocated. If no response is obtained within 24 hours, escalating dosages can be used. In hyperacute DIC cases, such as amniotic fluid embolism, septic abortion, and purpura fulminans, intravenous bolus injection of 5000 to 10,000 U heparin may be given simultaneously with replacement therapy with blood products. Some experts, however, would not administer a bolus dose of heparin even under these circumstances. Continuous infusion of 500 to 1000 U/hr of heparin may be necessary to maintain the benefit until the underlying disease responds to treatment. Apart from all of these considerations, current guidelines dictate the universal use of prophylactic doses of heparin or low-molecular-weight heparin to prevent venous thromboembolic events in critically ill patients.[6]

Theoretically, the most logical anticoagulant agent to use in DIC is directed against TF activity. Potential agents include recombinant TFPI; inactivated factor VIIa; and recombinant NAPc2, a potent and specific inhibitor of the ternary complex of TF/factor VIIa and factor Xa. Phase II trials of recombinant TFPI in patients with sepsis showed promising results, but phase III trials in patients with severe sepsis or severe pneumonia and organ failure did not show an overall survival benefit in patients who were treated with TFPI.[27]

Recombinant human soluble thrombomodulin binds to thrombin to form a complex that inactivates thrombin's coagulant activity and activates protein C and thus is a potential drug for the treatment of patients with DIC. In a phase III, randomized, double-blind clinical trial in patients with DIC, administration of the soluble thrombomodulin had a significantly better effect on bleeding manifestations and coagulation parameters than heparin. Currently ongoing trials with soluble thrombomodulin focus on DIC, organ failure, and mortality rate.

Physiological Anticoagulant Factor Concentrates

Restoration of the levels of physiological anticoagulants in DIC may be a rational approach.[28,29] Based on successful preclinical studies, the use of AT concentrates and heparin in patients with DIC has been examined mainly in randomized controlled trials that included patients with sepsis, septic shock, or both. All trials have shown some beneficial effect in terms of improvement of laboratory parameters, shortening of the duration of DIC, or even improvement in organ function. In several small clinical trials, use of very high doses of AT concentrate showed even a modest reduction in mortality, however, without being statistically significant. A large-scale, multicenter, randomized, controlled trial also showed no significant reduction in mortality of patients with sepsis.[30] Interestingly, post-hoc subgroup analyses of the latter study indicated some benefit in patients who did not receive concomitant heparin, but this observation needs validation. In a small randomized trial in patients with burns and DIC, AT administration decreased mortality, reduced multiple organ failure, and improved coagulation parameters compared with placebo-control patients.

Because a decreased function of the protein C system contributes to the pathogenesis of DIC, therapy by APC was predicted to be beneficial.[31] Indeed, a dose-ranging controlled trial using continuous infusion of recombinant human APC disclosed that a dose of 24 μg/kg/hr was optimal, judged by a decrease of D-dimer level in plasma. A subsequent phase III trial of APC concentrate in patients with sepsis was prematurely stopped because of efficacy in reducing mortality in these patients.[32] All-cause mortality at 28 days after inclusion was 24.7% in the APC group versus 30.8% in the control group (a 19.4% relative risk reduction). Amelioration of coagulation abnormalities and less organ failure were noted in patients who received the concentrate. Part of the success of therapy could be ascribed to the anti-inflammatory effect of APC. Interestingly, patients who manifested "overt DIC" (see Diagnosis) benefited more from the therapy with APC than patients who did not have overt DIC.[9] The relative risk reduction in mortality of patients with both sepsis and DIC was 38%, but patients with sepsis and no DIC had a risk reduction of 18%. This seems to underscore the importance of the coagulation derangement in the pathogenesis of sepsis and implies that the restoration of the protein C pathway in the microvasculature is essential for cure in patients with sepsis. However, meta-analyses of published literature conclude that the basis for treatment with APC even in patients with a high disease severity, is not very strong or even insufficient. The series of negative trials in specific populations of patients with severe sepsis has added to the skepticism regarding the use of APC. In addition, there is uncertainty regarding the bleeding risk of APC in patients with severe sepsis. In a phase 3 study conducted in patients with severe sepsis, the incidence of major bleeding (i.e., bleeding reported as a serious adverse event) during the infusion period was 2.4% in the APC group compared with 1.0% in the control group ($P = .02$). During the 28-day study period, the incidence of major bleeding was 3.5% in the APC group and 2.0% in the placebo group ($P = .06$). Gastrointestinal bleeding was the most frequent bleeding complication in both groups. Most bleeding episodes were procedure related or occurred in patients with a severely deranged coagulation system (partial thromboplastin time >120 sec or INR >3.0), but spontaneous bleeding was rare. The bleeding rate in the clinical trials seems to be acceptable, but it may be that in the "real world," the risk of bleeding, including intracranial bleeding, is higher. A recently completed placebo-controlled trial in patients with severe sepsis and septic shock was prematurely stopped because of the lack of any significant benefit of APC. Subsequently, the manufacturer of APC has decided to withdraw the product from the market, which has resulted in a revision of current guidelines for treatment of DIC.

Fibrinolytic Inhibitors

Most guidelines recommend against the use of antifibrinolytic agents, such as ε-aminocaproic acid or tranexamic acid, in patients with

DIC. This is because these drugs block already suppressed endogenous fibrinolysis, and may further compromise tissue perfusion. In support of this concept, there are reports of severe thrombosis in DIC patients treated with these agents. However, in patients with DIC accompanied by primary fibrino(geno)lysis, as in some cases of APL, giant cavernous hemangioma, heatstroke, and metastatic carcinoma of the prostate, the use of fibrinolytic inhibitors can be considered if the patient has profuse bleeding that does not respond to replacement therapy and there is evidence of excessive fibrino(geno)lysis.[33] In these situations, it is important to replace depleted blood components before initiating treatment with fibrinolytic inhibitors.

CHAPTER 142

HYPERCOAGULABLE STATES

Julia A. Anderson and Jeffrey I. Weitz

Arterial and venous thromboses are common problems for all clinicians. Some patients with thrombosis have an underlying hypercoagulable state. These hypercoagulable states can be divided into three categories: inherited disorders, acquired disorders and those that are mixed in origin.[1,2]

Inherited hypercoagulable states, which are also known as thrombophilic disorders, can be due to loss of function of natural anticoagulant pathways or gain of function in procoagulant pathways (Table 142-1). Acquired hypercoagulable states represent a heterogeneous group of disorders in which the risk for thrombosis appears to be higher than that in the general population. These include such diverse risk factors as a prior history of thrombosis, obesity, pregnancy, cancer and its treatment, antiphospholipid antibody syndrome, drug-induced thrombosis such as heparin-induced thrombocytopenia or thrombosis associated with chemotherapeutic agents and myeloproliferative disorders. The pathogenesis of thrombosis in these situations is largely unknown and, in many cases, is likely multifactorial in origin. Mixed disorders are those with both an inherited and an acquired component; one example is hyperhomocysteinemia. Although severe hyperhomocysteinemia and associated homocysteinuria are rare genetic disorders, most cases of mild to moderate hyperhomocysteinemia result from acquired folate and/or vitamin B_{12} deficiency superimposed on common genetic mutations in biochemical pathways involved in methionine metabolism.[2]

Genetic hypercoagulable states and acquired risk factors combine to establish an intrinsic risk for thrombosis for each individual.[3,4] This risk can be modified by extrinsic or environmental factors, such as surgery, immobilization, or hormonal therapy, which also increase the risk for thrombosis. When the intrinsic and extrinsic forces exceed a critical threshold, thrombosis occurs (Fig. 142-1). Appropriate thromboprophylaxis can prevent the thrombotic risk from exceeding this critical threshold, but breakthrough thrombosis can occur if procoagulant stimuli overwhelm protective mechanisms.

This chapter describes the inherited, acquired, and mixed hypercoagulable states, details their laboratory evaluation, and provides practical advice for the management of these conditions.

INHERITED HYPERCOAGULABLE STATES

Inherited disorders are found in up to half of patients who present with venous thromboembolism before the age of 40, particularly those whose event occurred either in the absence of well-recognized risk factors, such as surgery or immobilization, or with minimal provocation, such as after minor trauma, after a long distance flight, or after taking estrogens.[5] Patients with inherited thrombophilic disorders often have a family history of thrombosis. Of greatest significance is a family history of sudden death due to pulmonary embolism or a history of multiple family members requiring long-term anticoagulation therapy because of recurrent thrombosis. Patients who present with venous thrombosis in unusual sites, such as the cerebral venous sinuses or mesenteric veins, those with recurrent thrombosis, and patients who develop skin necrosis upon initiation of warfarin therapy should also be suspected of having an inherited hypercoagulable state.[6,7]

From a pathophysiologic perspective, inherited hypercoagulable states fall into two categories. First are those associated with loss of function of endogenous anticoagulant proteins. These include deficiencies of antithrombin, protein C, and protein S. The second category involves gain of function in procoagulant pathways. These disorders include factor V_{Leiden} and the FIIG20210A mutation, as well as increased levels of procoagulant proteins, such as factors VIII, IX, and XI. Each of these conditions will be briefly described.

Loss of Function of Endogenous Anticoagulants

Antithrombin Deficiency

Antithrombin, a single-chain glycoprotein with a molecular weight of 52,000 Da, is a member of the serine proteinase inhibitor (serpin) superfamily that was first described by Brinkhous in 1939.[8] Antithrombin is synthesized in the liver[9] and endothelial cells, and its gene (SERPINC1, previously known as *AT3*)[10] is localized on the long arm of chromosome 1 (1q23-1q25). SERPINC1 is composed of 7 exons and 7 introns and spans 16 kb.

Antithrombin plays a critical role in regulating coagulation by forming a 1 : 1 covalent complex with thrombin, factor Xa, and other activated clotting factors. Once covalent complexes are generated, they are cleared from the circulation via the liver. The rate of antithrombin interaction with its target proteases is accelerated by heparin by 1000-fold.[11] Heparan sulfate proteoglycan, which coats the vasculature, is the physiologic counterpart of medicinal heparin.[12]

Newborn infants have approximately 50% of normal adult antithrombin levels, and much lower levels are found in preterm infants because of liver immaturity; adult levels are attained at 6 months.[13-16]

Antithrombin deficiency can be inherited or acquired[17,18] and congenital deficiency of antithrombin was the first reported inherited risk factor for venous thromboembolism.[19] Congenital antithrombin deficiency is relatively rare, occurring in about 1 in 2000,[20,21] and can be one of two types (Table 142-2),[10] both of which are inherited in an autosomal dominant fashion[17] and affect both sexes equally.[22,23] Type I deficiency, which represents the classic deficiency state, is the result of reduced synthesis of biologically normal antithrombin.[24] Heterozygotes with this condition have parallel reductions in antithrombin antigen and activity with levels reduced to about 50% those of normal. A heterogeneous group of nonsense mutations, small deletions, insertions, or single-base substitutions are the molecular cause of most cases, although gene deletions can also be responsible. In total, more than 113 mutations have been identified as causes of type I antithrombin deficiency.[25] An antithrombin mutation database compiled by members of the Plasma Coagulation Inhibitors Subcommittee of the Scientific and Standardization Committee of the International Society on Thrombosis and Hemostasis summarizes the mutations and can be accessed on the Imperial College London website (www1.imperial.ac.uk/medicine/about/divisions/department ofmedicine/experimentalmedicine/haematology/coag/antithrombin/) or in the human gene mutation database (www.hgmd.cf.ac.uk).

Table 142-1 Classification of Hypercoagulable States

Hereditary	Mixed	Acquired
LOSS OF FUNCTION		
Antithrombin deficiency	Hyperhomocysteinemia	Previous venous thromboembolism
Protein C deficiency	Obesity	Pregnancy, puerperium
Protein S deficiency	Cancer	Drug-induced:
		Heparin-induced thrombocytopenia
		Prothrombin complex concentrates
		L-asparaginase
		Hormonal therapy
GAIN OF FUNCTION		
Factor V Leiden	Postoperative	
Prothrombin FII20210A	Myeloproliferative disorders	
Elevated factor VIII, IX, or XI		

Table 142-2 Types of Inherited Antithrombin Deficiency

Type	Antigen	Activity (no heparin)	Activity (with heparin)
I	Low	Low	Low
II (active site defect)	Normal	Low	Low
II (heparin-binding site defect)	Normal	Normal	Low

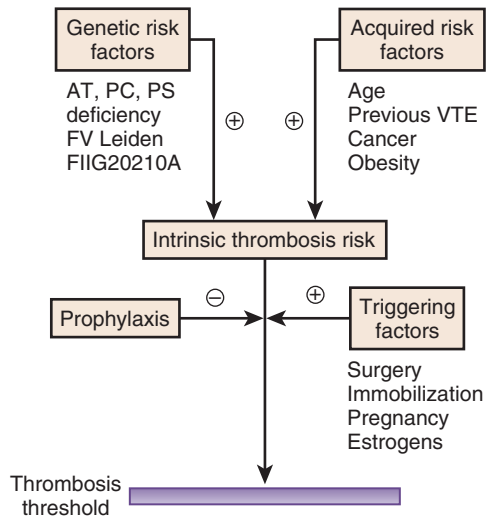

Figure 142-1 THROMBOSIS THRESHOLD. Genetic and acquired risk factors continue to determine an intrinsic risk for thrombosis for each individual. This risk is increased by extrinsic or environmental factors and decreased by thromboprophylaxis. If the intrinsic and extrinsic forces exceed a critical threshold at which thrombin generation overwhelms the protective mechanisms, thrombosis will result. *(From Anderson JA, Weitz JI: Hypercoagulability and uncommon vascular diseases. In Jaff MR, White CJ, editors:* Vascular disease: Diagnostic and therapeutic approaches, *Minneapolis, Minn, 2011, Cardiotext Publishing.)*

Table 142-3 Causes of Acquired Antithrombin Deficiency

Decreased Synthesis	Increased Consumption	Enhanced Clearance
Hepatic cirrhosis	Major surgery	Heparin
Severe liver disease	Acute thrombosis	Nephrotic syndrome
L-asparaginase	Disseminated intravascular coagulation	
	Severe sepsis	
	Multiple trauma	
	Malignancy	
	Prolonged extracorporeal circulation	

Type II antithrombin deficiencies are characterized by normal levels of antithrombin with impaired functional activity due to the presence of a variant protein. This condition is mainly caused by missense mutations that result in single amino acid substitutions.[17] The clinical consequences of type II antithrombin deficiency depend on the location of the mutation,[26,27] which may involve the reactive center loop or the heparin-binding domain. For example, some mutations in the reactive center loop of antithrombin slow its interaction with target proteases and are characterized by reduced antithrombin activity in the absence or presence of heparin. In contrast, mutations in the heparin-binding domain are associated with reduced antithrombin activity in the presence of heparin but normal activity in its absence.[28] Unlike other inherited forms of antithrombin deficiency, which are embryonic lethal in the homozygous state, mutations in the heparin-binding domain have clinical consequences only in individuals homozygous for these mutations[29] and do not increase the risk for thrombosis in the heterozygous state.

Because of the wide variety of heritable forms of antithrombin deficiency, functional antithrombin assays are the preferred method for screening. Most functional assays use synthetic substrates to monitor the rates at which added thrombin or factor Xa are inhibited in patient plasma.[16,30] However, the assays differ in terms of whether bovine or human thrombin is used and whether or not heparin is added. Defects in the heparin-binding domain of antithrombin will be detected only in the presence of heparin. When antithrombin deficiency is identified with functional assays, immunologic assays are performed to distinguish between type I and type II deficiency.

Congenital antithrombin deficiency can cause spontaneous venous thromboembolism, but thrombosis often occurs in the setting of pregnancy and the puerperium; the use of the combined oral contraceptive pill; or after major trauma or surgery. Thrombotic events are rare in children with events typically occurring from mid- to late teenage years and into the early twenties. The European Prospective Cohort on Thrombophilia (EPCOT) study compared the risks of a first episode of venous thromboembolism in asymptomatic individuals with antithrombin, protein C, or protein S deficiency with that in subjects with factor V_{Leiden} over a 6-year period. The annual incidence of venous thromboembolism was highest in those with antithrombin deficiency.[31]

The most common sites for venous thrombosis are the deep veins of the leg, but thrombosis can occur in mesenteric veins, as well as the renal and retinal veins. The risk for recurrent thrombosis is high. The risk for recurrence is not well correlated with the antithrombin level but appears to vary depending on the subtype of antithrombin deficiency.

Acquired antithrombin deficiency can reflect decreased antithrombin synthesis, increased consumption, or enhanced clearance (Table 142-3). Decreased synthesis can occur in patients with severe hepatic disease, particularly cirrhosis, or in those given L-asparaginase,[32] the latter as a result of drug-induced retention of antithrombin within the endoplasmic reticulum.[33] Increased thrombin generation can result in antithrombin consumption. Disorders associated with excessive thrombin generation include acute thrombosis, disseminated

intravascular coagulation, severe sepsis, multiple trauma, disseminated malignancy, extensive burns, or prolonged extracorporeal circulation.[34,35] Heparin treatment can reduce antithrombin levels up to 20% by enhancing its clearance.[36] Severe antithrombin deficiency can also occur in some patients with nephrotic syndrome because of the loss of protein in the urine.[37]

Users of oral contraceptive pills or hormone replacement therapy may have moderate reductions in antithrombin levels; during pregnancy, the antithrombin levels do not fall significantly but decreases are found in preeclampsia and pregnancy-induced hypertensive illnesses.

Protein C Deficiency

The protein C pathway is an important natural anticoagulant pathway.[38] This on-demand pathway is activated when thrombin is generated (Fig. 142-2). Thrombin binds to thrombomodulin, a transmembrane thrombin receptor found on the surface of endothelial cells. Once bound to thrombomodulin, the substrate specificity of thrombin is altered so that it no longer serves as a procoagulant enzyme, but becomes a potent activator of protein C, a vitamin K–dependent glycoprotein. Thus thrombin bound to thrombomodulin activates protein C 1000-fold more efficiently than free thrombin.[39] The endothelial cell protein C receptor (EPCR), another transmembrane receptor on the endothelial cell surface, binds protein C and presents it to the thrombin-thrombomodulin complex for activation, thereby producing an additional 20-fold increase in the rate of protein C activation.[40,41] The physiologic importance of thrombomodulin and EPCR is highlighted by the fact that deficiency of either receptor results in embryonic lethality in mice, as does deficiency of protein C.

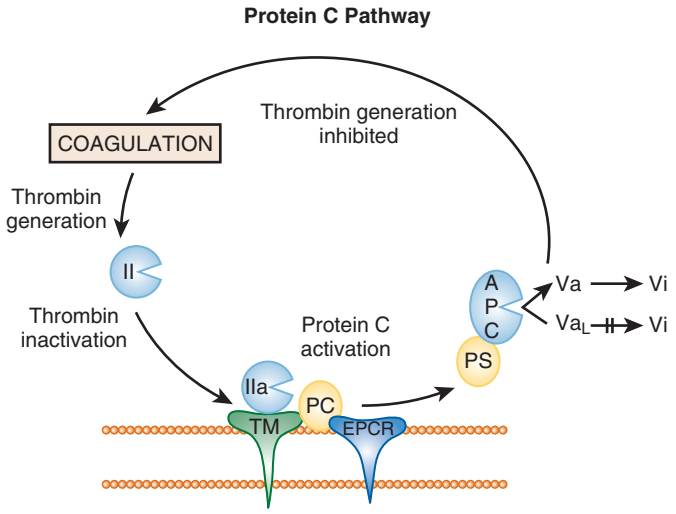

Figure 142-2 PROTEIN C PATHWAY. Activation of coagulation triggers thrombin (IIa) generation. Excess thrombin binds to thrombomodulin (TM) on the endothelial cell surface. Once bound, the substrate specificity of thrombin is altered so that it no longer acts as a procoagulant but becomes a potent activator of protein C (PC). Endothelial protein C receptor (EPCR) binds protein C and presents it to thrombomodulin-bound thrombin, where it is activated. Activated protein C (APC), together with its cofactor, protein S (PS), binds to the activated platelet-surface and proteolytically degrades factor Va (Va) into inactive fragments (Vi). Because factor Va is a critical component of the prothrombinase complex, factor Va inactivation by activated protein C attenuates thrombin generation. Because factor Va_{Leiden} (FVa_L) is resistant to inactivation by activated protein C, patients with the factor V_{Leiden} mutation have reduced capacity to regulate thrombin generation. *(From Anderson JA, Weitz JI: Hypercoagulability and uncommon vascular diseases. In Jaff MR, White CJ, editors:* Vascular disease: Diagnostic and therapeutic approaches, *Minneapolis, Minn, 2011, Cardiotext Publishing.)*

Activated protein C (APC) dissociates from this activation complex and acts as an anticoagulant by proteolytically degrading and inactivating factors Va and VIIIa, thereby attenuating thrombin generation. For efficient inactivation of factors Va and VIIIa, APC must bind to protein S, its cofactor. This interaction facilitates APC binding to activated cell surfaces, particularly the platelet surface, where factors Va and VIIIa are localized.[39]

APC has a half-life in the circulation of about 15 minutes, whereas thrombin has a half-life of about 10 seconds. APC is inhibited by protein C inhibitor and α_1-proteinase inhibitor (α_1-antitrypsin), both of which are relatively slow inhibitors. Only the activity of protein C inhibitor is enhanced by heparin, but both inhibitors appear to contribute to APC inhibition in vivo.

Protein C deficiency can be inherited or acquired. Like antithrombin deficiency, protein C deficiency is inherited in an autosomal-dominant fashion[42] and has a proven association with recurrent venous thrombosis.[43] Based on studies in healthy blood donors, heterozygous protein C deficiency can be found in 1 in 200 to 500 of the adult population,[44,45] but many of these individuals do not have a history of thrombosis. Thus the phenotypic expression of hereditary protein C deficiency is highly variable and may depend on other, as yet unrecognized, modifying factors.[5] In contrast to antithrombin deficiency in which the homozygous state is embryonic lethal, homozygous or doubly heterozygous protein C deficiency can occur. The prevalence of homozygous protein C deficiency is estimated to be 1:160,000 to 1:360,000 births.[46] Newborns with these disorders may present with purpura fulminans characterized by widespread thrombosis.[47]

Individuals with heterozygous protein C deficiency can develop skin necrosis upon initiation of warfarin therapy.[48-50] Typically, skin lesions are found on the extremities, breasts, or trunk. Starting as erythematous macules, the central regions of the cutaneous lesions become purpuric and then necrotic over a period of hours unless protein C is administered. Biopsies reveal fibrin thrombi within the vessels of the skin associated with interstitial hemorrhage. The skin lesions are clinically and histologically similar to those seen in infants with purpura fulminans and are attributable to the transient hypercoagulable state that is induced by warfarin, thereby explaining why they occur early during the course of warfarin therapy. The half-life of protein C is short and similar to that of factor VII. Starting warfarin in patients with protein C deficiency causes a further reduction in protein C levels, particularly if loading doses of warfarin are given. Thus the activity of the natural anticoagulant protein C pathway is compromised before warfarin lowers the levels of the vitamin K procoagulant proteins into the range required for its antithrombotic effects. Warfarin-induced skin necrosis has also been reported in association with acquired deficiency of protein C.[51]

Hereditary protein C deficiency can be further delineated into two subtypes using immunologic and functional assays (Table 142-4). Most functional assays use Protac, a snake venom protease, to activate protein C in plasma.[52] The enzymatic activity of APC can then be assayed directly using an APC-directed synthetic substrate, or it can be indirectly quantified by measuring the extent of prolongation of the activated partial thromboplastin time (aPTT).[53] The most common form of hereditary protein C deficiency is the classic or type I deficiency state. This disorder reflects reduced synthesis of a normal protein and is characterized by a parallel reduction in protein C antigen and activity, a quantitative deficiency due to reduced synthesis or stability of protein C.[54] A variety of genetic defects can produce type I protein C deficiency, including promoter mutations, splice-site

Table 142-4 Types of Inherited Protein C Deficiency

Type	Antigen	Activity
I	Low	Low
II	Normal	Low

abnormalities, in-frame deletions, frameshift deletions, in-frame insertions, and frameshift insertions in the protein C gene (PROC), but missense or nonsense mutations are the most common.

Type II protein C deficiency reflects synthesis of a dysfunctional protein and is characterized by normal protein C antigen with reduced functional activity, a qualitative deficiency. Most type II protein C deficiency states are caused by point mutations. Mutations in the active site of APC reduce its activity against synthetic substrates and decrease its capacity to prolong the aPTT. In contrast, mutations that affect other protein C domains essential for its activity may reduce its anticoagulant activity but may not affect its amidolytic activity. Therefore coagulation-based functional assays are preferred when screening patients for protein C deficiency.

Diagnosis of protein C deficiency is complicated. Protein C circulates in human plasma at an average concentration of 4 μg/mL. Protein C antigen levels are distributed in healthy adults so that 95% of the values range from 70% to 140%.[46] Furthermore, protein C levels increase with age by about 4% per decade with no influence of gender. The wide range of values makes it difficult to establish a normal range. Levels less than 55%, however, are likely to reflect deficiency, whereas those between 55% and 70% are considered borderline[7,38,55] and may be consistent with a deficiency state or the lower end of the normal distribution.[46] Acquired causes of protein C deficiency must be excluded, and to document the presence of protein C deficiency, it is necessary to repeat the testing. Family studies may also be helpful to highlight the autosomal dominant pattern of inheritance.

Acquired protein C deficiency can be due to decreased synthesis or increased consumption. Decreased synthesis can occur in patients with liver disease or in those given warfarin.[56] Warfarin decreases functional activity more than immunologic activity; newborns have protein C levels 20% to 40% lower than those of adults, and premature infants have even lower levels.[57,58] Protein C consumption can occur with severe sepsis, with disseminated intravascular coagulation, and after surgery.[58] Reduced protein C levels have also been reported in cancer patients receiving cyclophosphamide, methotrexate, 5-fluorouracil, or L-asparaginase.[59] A particularly severe form of acquired protein C deficiency has been described in association with meningococcal septicemia.[60] In contrast to antithrombin, which is excreted in the urine of patients with nephrotic syndrome, the levels of protein C are normal or elevated in patients with nephrotic syndrome.[61]

Protein S Deficiency

Protein S serves as a cofactor for APC and enhances its capacity to inactivate factors Va and VIIIa.[40,62] In addition, protein S may have direct anticoagulant activity by inhibiting prothrombin activation through its capacity to bind anionic phospholipid, factor Va or factor Xa, components of the prothrombinase complex.[39,63] The importance of the direct anticoagulant activity of protein S is uncertain.

In the circulation, about 60% of total protein S is bound to C4b-binding protein, an acute phase complement component. Only the 40% of the protein S that is free is functionally active.[7] The diagnosis of protein S deficiency, therefore, requires measurement of both free and bound forms of protein S. Total protein S levels can be measured immunologically under conditions that dissociate protein S from C4b-binding protein.[64] A monoclonal antibody that only recognizes noncomplexed protein S can then be used to measure free protein S.[65] The functional activity of protein S can be measured using an APC cofactor assay. This assay depends on prolongation of the aPTT when diluted patient plasma is added to protein S-depleted plasma containing APC and factor Va.[53,66]

Protein S deficiency can be inherited or acquired. Heterozygous protein S deficiency is inherited in an autosomal dominant manner; the prevalence varies between 1% and 7% among patients with thrombotic events,[67] and there is a proven association with recurrent thrombosis.[68] Based on measurements of total and free protein S antigen and protein S activity, three subtypes of inherited protein S deficiency have been identified (Table 142-5). Type I or classical deficiency results from decreased synthesis of a normal protein and is characterized by reduced levels of total and free protein S antigen together with reduced protein S functional activity. Molecular analysis of protein S deficiency is complicated because there are two homologous protein S genes, one of which is likely a pseudogene. Nonetheless, most cases of type I protein S deficiency are caused by partial gene deletions, missense mutations, base pair insertions or deletions, premature stop codons, or mutations affecting a splice site in the gene encoding protein S (PROS1).[69] Type II protein S deficiency is characterized by normal levels of total and free protein S, associated with reduced protein S activity. This type of deficiency is uncommon, and most of the causative mutations encode protein S domains involved in its interaction with APC.[70]

Table 142-5 Types of Inherited Protein S Deficiency

Type	Total Protein S	Free Protein S	Protein S Activity
I	Low	Low	Low
II	Normal	Normal	Low
III	Normal	Low	Low

Type III protein S deficiency is characterized by normal levels of total protein S, but low levels of free protein S associated with reduced protein S activity. The molecular basis of this type of deficiency appears to be similar to that of the type I deficiency states.[71] In fact, type I and type III protein S deficiency are likely to be manifestations of the same disease because they often coexist in families. Thus younger family members present with type I deficiency, whereas older family members have type III deficiency because protein S levels increase with age.

Acquired protein S deficiency can be due to decreased synthesis, increased consumption, loss, or shift of free protein S to the bound form. Decreased synthesis can occur in patients with severe liver disease,[72,73] in those given L-asparaginase,[74] and in patients given vitamin K antagonists.[72] Increased consumption of protein S occurs in patients with acute thrombosis or in those with disseminated intravascular coagulation.[73] Patients with nephrotic syndrome can lose free protein S in their urine, causing decreased protein S activity.[75] Total protein S levels in these patients are often normal because the levels of C4b-binding protein increase, shifting more protein S to the bound form. C4b-binding protein levels also increase in pregnancy and with the use of oral contraceptives.[76,77] This shifts more protein S to the bound form and lowers the levels of free protein S and protein S activity.[78,79] The pathophysiologic consequences of this phenomenon are uncertain. An association between antiphospholipid antibodies and acquired protein S deficiency has been reported in patients with severe forms of varicella zoster virus infection complicated by purpura fulminans.[80] In healthy neonates the total protein S antigen levels are 15% to 30% of normal, and the C4b-binding protein is significantly reduced to less than 20%, such that the free form of protein S predominates and the functional levels are only slightly reduced compared with normal adult levels.[81]

Gain of Function Mutations

Gain of function mutations include factor V_{Leiden}, FIIG20210A, elevated levels of procoagulant proteins, and other less well-characterized genetic disorders. The gain of function mutations are more prevalent in the general population than those associated with loss of function.

Factor V_{Leiden}

In 1993, Dahlback and colleagues described three families with a history of venous thromboembolism.[82,83] Affected family members exhibited limited prolongation of the aPTT when APC was added to their plasma. Accordingly, this phenotype was designated APC

resistance (APCR). Bertina and colleagues demonstrated that APCR co-segregated with the factor V gene and was due to a single base substitution, guanine to adenine at position 1691, that produced an Arg 506 Gln mutation at one of the APC cleavage sites on factor Va.[84-86] This mutation, which is designated factor V_{Leiden}, endows activated factor V_{Leiden} with a 10-fold longer half-life in the presence of APC than its wild-type counterpart.

The factor V_{Leiden} mutation is responsible for most cases of APCR.[87,88] Other causes are mutations at Arg 306, another APC cleavage site. Arg 306 is replaced by a Gly residue in factor $V_{Hong\ Kong}$[89] and by a Thr residue in factor $V_{Cambridge}$.[90] Neither of these mutations is strongly associated with thrombosis.

The factor V_{Leiden} mutation is inherited in an autosomal-dominant fashion. The prevalence of the mutation ranges from 2% to 5% in whites,[91] but it is rare in Asians and Africans.[92,93] This racial difference likely reflects a founder effect with the mutation arising 20,000 to 30,000 years ago, after the divergence of non-Africans from Africans and Caucasoids from Mongoloid subpopulations.[94] The prevalence of factor V_{Leiden} homozygosity is about 1 in 2500.[7] The risk for thrombotic complications is lower with factor V_{Leiden} than it is with deficiencies of antithrombin, protein C, or protein S.[95-97] Heterozygotes with the factor V_{Leiden} mutation have a yearly risk of 0.1% to 0.3%, whereas the risk with deficiencies of antithrombin, protein C, or protein S ranges from 0.5% to 1.5% per year. The risk for thrombosis is higher in homozygotes than in heterozygotes. Acquired APC resistance may be caused by hormonal changes during pregnancy[98] or by the administration of estrogens, such as oral contraceptive pills[99] or hormone replacement therapy.[54,98]

A diagnosis of APCR is established using a functional assay based on the ratio of the aPTT after APC addition divided by that determined before APC addition.[100] Second-generation tests, which add dilute patient plasma to factor V-deficient plasma, are more specific for factor V_{Leiden}.[101] A normal functional test excludes factor V_{Leiden}; a positive functional test for APCR should be confirmed with a genetic test for the factor V_{Leiden} mutation.[102]

FIIG20210A Mutation

After extensive screening of 28 families with unexplained venous thromboembolism, Poort and colleagues identified a heterozygous G to A nucleotide transition at position 20210 in the 3′-untranslated region of the prothrombin gene in 5 of the probands.[103] This mutation, FIIG20210A, results in elevated levels of prothrombin. Elevated levels of prothrombin, in turn, may increase the risk for thrombosis by enhancing thrombin generation[104,105] or by inhibiting factor Va inactivation by APC.[106]

The mechanism by which the FIIG20210A mutation causes increased prothrombin levels appears to vary. Enhanced protein synthesis may result from more efficient 3′-end formation, increased messenger RNA stability, increased translation efficiency, or some combination of these mechanisms.[107] An intronic FII gene polymorphism, A19911G, which influences splicing efficiency, may modulate the effect of the FIIG20210A mutation such that heterozygous carriers of both mutations have a greater risk for thrombosis than those with only the FIIG20210A mutation.[108]

Like the factor V_{Leiden} mutation, the prevalence of the FIIG20210A mutation is higher in whites and low in Asians, American Indians, and African Americans.[109] A founder effect likely explains the higher prevalence in whites. The mutation may have provided a survival advantage based on a protective effect with childbirth or severe sepsis.[110,111]

FIIG20210A is found in 1% to 6% of whites.[103,112] The mutation is more common in southern Europe than in northern Europe, a gradient opposite to that of factor V_{Leiden}.[113] Rare individuals homozygous for the FIIG20210A mutation have been identified.[114,115] In the Leiden Thrombophilia Study, 6.2% of venous thrombosis patients and 2.3% of healthy matched controls had the FIIG20210A mutation.[116] The mutation independently confers a 2.8-fold increased risk for venous thrombosis, with no gender bias. Similar to the factor V_{Leiden} mutation, the risk for venous thrombosis is increased by the use of oral contraceptives.[117]

Laboratory diagnosis of FIIG20210A depends on genetic screening after PCR amplification of the 3′-untranslated region of the FII gene.[53] Although FIIG20210A heterozygotes have 30% higher levels of prothrombin than noncarriers, the wide range of prothrombin levels in healthy individuals precludes the use of this phenotype to identify carriers.[116,118]

Elevated Levels of Procoagulant Proteins

Elevated levels of factor VIII and other coagulation factors, including factors XI, IX and VII, have been implicated as independent risk factors for thrombosis.[119-122] Although the molecular bases for the high levels of these coagulation factors have yet to be identified, genetic mechanisms are likely responsible because the hereditability of these quantitative abnormalities is high.

Other Hereditary Disorders

The dysfibrinogenemias represent a heterogeneous group of disorders characterized by abnormal fibrinogen structure and are diagnosed by low functional and/or immunologic levels of fibrinogen, in association with prolonged thrombin and reptilase times. Acquired causes of dysfibrinogenemia, such as liver disease, must be excluded in the diagnostic work-up. Most congenital dysfibrinogenemias are asymptomatic, and they are often identified as an incidental finding when coagulation testing is performed for other reasons. Up to 40% of the known dysfibrinogenemias are associated with a bleeding diathesis. Approximately 15 variant fibrinogens, which represent less than 10% of known dysfibrinogenemias, have been reported to be associated with thrombotic complications, including fibrinogen Marburg, Caracas V, Chapel Hill III, Hannover II, Nijmegen, New York I, Christchurch II and III, and Milano III.[123] The exact mechanism by which these dysfibrinogenemias increase the risk for thrombosis depends on the nature of the fibrinogen defect. Most affect the C-terminal domain of the Aα chains or the thrombin cleavage site on the Bβ chains.[124] Some biochemical defects have been further characterized, such as defects in the release of fibrinopeptides A or B by thrombin, impaired binding of thrombin or tissue plasminogen activator to fibrin,[125,126] or resistance to lysis by plasmin.[124,127] It is likely that acquired and/or other hereditary factors contribute to thrombosis that occurs in patients with dysfibrinogenemia. For example, a woman heterozygous for fibrinogen Cedar Rapids and the factor V_{Leiden} mutation was reported to have thrombosis during pregnancy, but family members with only one hereditary defect were asymptomatic.[128]

Polymorphisms in the gene encoding EPCR have been associated with thrombosis. An EPCR polymorphism associated with high levels of soluble EPCR has been identified. By binding circulating protein C and APC, soluble EPCR competes with cell surface EPCR for protein C and prevents circulating APC from functioning as an anticoagulant.[129,130]

ACQUIRED HYPERCOAGULABLE STATES

Acquired hypercoagulable states include antiphospholipid antibody syndrome and cancer, as well as pregnancy and estrogen therapy (oral contraception or hormone replacement therapy). These disorders can occur in isolation or can be superimposed on hereditary hypercoagulable states. Heparin-induced thrombocytopenia is an immune-mediated adverse drug reaction, and is a strong, independent risk factor for arterial and venous thrombosis.

Lupus Anticoagulants and the Antiphospholipid Syndrome

First described in a study by Wasserman and colleagues in 1906 among patients with positive serologic tests for syphilis,[131] antiphospholipid antibodies are a heterogeneous group of autoantibodies directed against proteins that bind phospholipid.[132] Antibodies can

be categorized into those that prolong phospholipid-dependent coagulation assays, known as lupus anticoagulants (LAs), or anticardiolipin antibodies (ACLs), which target cardiolipin. A subset of ACL recognizes other phospholipid-bound proteins, particularly β_2-glycoprotein I.

Patients who have thrombosis in association with an LA and/or ACL (antibodies of the IgG or IgM subclass directed against cardiolipin, or β_2-glycoprotein I–directed antibodies of the IgG or IgM subclass) are diagnosed with antiphospholipid syndrome (APS). The criteria for diagnosis of APS were developed in 1999[133] through international consensus and were updated in 2004.[134] APS is considered primary when it occurs in isolation and secondary when it is associated with autoimmune disorders, such as systemic lupus erythematosus or other connective tissue diseases. Clinical manifestations of APS include one or more episode of thrombosis, one or more unexplained fetal deaths at 10 or more weeks of gestation, or three or more first-trimester miscarriages (less than 10 weeks of gestation).[135] Placental thrombosis is hypothesized to be the root cause of the pregnancy-related complications that characterize APS. Intrauterine growth retardation, preeclampsia, and eclampsia have also been associated with APS. APS can also occur with cancer, with some infections, and with drugs, such as phenothiazines, phenytoin, hydralazine, or amoxicillin. Thrombosis in APS patients can be arterial, venous, or placental.[136]

To make the diagnosis of APS, at least one clinical criterion and one laboratory criterion must be met. Laboratory diagnosis of APS requires the presence of LA or ACL on tests taken at least 6 to 12 weeks apart.[137] LAs are detected using phospholipid-dependent clotting tests. Most screening assays are based on the aPTT. aPTT reagents differ in their sensitivity for detection of LA, and many laboratories have adopted less-sensitive aPTT reagents for routine aPTT testing. LA is suspected when the aPTT is prolonged. To explore the cause of the prolonged aPTT, patient plasma is mixed with normal plasma and the aPTT is again determined. If the aPTT remains prolonged, an LA is suspected. The diagnosis is confirmed by demonstrating that addition of excess hexagonal-phase phospholipid normalizes the aPTT, thereby documenting the phospholipid dependence of the abnormal test result. In addition to the aPTT, a battery of phospholipid-dependent clotting tests is often used for diagnosis of LA. These include the dilute Russell viper venom time and kaolin clotting time.[138]

ACL antibodies are detected using immunoassays.[139] Only ACL of medium to high titer and of the IgG or IgM subclass, or anti–β_2 glycoprotein-1 antibodies of the IgG or IgM subclass, are associated with thrombosis. For ACL, the amount of IgG or IgM antibody binding to cardiolipin-coated platelets is expressed in standardized GPL or MPL units, with 1 unit representing the cardiolipin-binding capacity of 1 μg/mL affinity-purified antiphospholipid antibody from reference sera. The extent of antibody binding is influenced by both the titer of the antibody and its affinity for cardiolipin. Lack of standardization of ACL assays makes it difficult to compare results between laboratories.[140,141]

ACL antibodies are found in 3% to 10% of healthy individuals. They also are common with certain infections (such as mycobacterial pneumonia, malaria, or parasitic disorders) and after exposure to some medications. Often, these antibodies are of low titer and are transient. ACL antibodies are detected in about 30% to 50% of patients with systemic lupus erythematosis.[142] Of these, 10% to 20% also have an LA.[143]

The mechanism by which antiphospholipid antibodies trigger thrombin is unclear. In cell culture systems, these antibodies can directly activate endothelial cells and induce the expression of adhesion molecules that can tether tissue factor-bearing leukocytes or microparticles onto their surface. Tissue factor can then induce clotting in vitro. Antiphospholipid antibodies also have been shown to (a) interfere with the protein C pathway, (b) inhibit antithrombin catalysis by vessel wall heparan sulfate, and (c) impair fibrinolysis.[141,144-146] Whether these mechanisms are operative in vivo has yet to be established.

In contrast to most hypercoagulable states, APS can be associated with spontaneous arterial thrombosis, as well as with venous thromboembolism.[6] Arterial thrombosis can manifest as a stroke or transient ischemic attack.[147,148] Thrombosis of the sagittal sinus, a form of venous thrombosis, also can cause stroke in these patients.[149]

Heparin-Induced Thrombocytopenia

A clinico-pathologic syndrome, heparin-induced thrombocytopenia (HIT) is diagnosed on the basis of clinical features (Table 142-6) and laboratory detection of HIT antibodies. The risk for HIT is higher with unfractionated heparin than with low-molecular-weight heparin (LMWH) and almost never occurs with fondaparinux. HIT is more common in surgical patients than in medical patients and occurs more frequently in women.

Typical clinical features of HIT include thrombocytopenia and thrombosis (arterial or venous). Less common features include necrotic skin lesions at the site of subcutaneous heparin injection, acute systemic reactions to heparin, and rarely, disseminated intravascular coagulation.[150,151] Thrombocytopenia is the most common finding, occurring in 90% of patients. Typically, the platelet count falls 5 to 10 days after heparin is started. However, thrombocytopenia can occur earlier if the patient has been exposed to heparin in the past 3 months. Rarely, the onset of HIT can be delayed and occurs several days after stopping heparin.[152]

HIT is an autoimmune-like disorder and is caused by heparin-dependent, platelet-activating antibodies of the IgG subclass. These antibodies are directed against neoantigens that are exposed on platelet factor 4 (PF4) when it forms a complex with heparin.[151] By binding to FcγII receptors on platelets, these antibodies trigger platelet activation. Activated platelets and platelet-derived microparticles provide an anionic phospholipid surface on which coagulation factors assemble and promote thrombin generation. This produces a hypercoagulable state and explains why 30% to 70% of HIT patients develop thrombosis.[153,154]

The diagnosis of HIT is supported by assays that capitalize on the platelet-activating properties of HIT antibodies. The platelet serotonin release assay is the gold standard for the diagnosis of HIT.[155] Enzyme immunoassays for detection of antibodies against PF4 are more sensitive, but are less specific than the serotonin release assay.[156]

When the diagnosis of HIT is established, heparin must be stopped and an alternative anticoagulant should be given. Options include direct thrombin inhibitors (such as lepirudin, argatroban, or bivalirudin) or factor Xa inhibitors (such as fondaparinux or danaparoid). Treatment with these agents should be continued until the platelet count returns to baseline levels at which point, low-dose warfarin can be initiated.

Cancer and Its Treatment

About 25% of patients who present with venous thromboembolism have cancer.[157] Cancer patients who develop venous

Table 142-6 Features of Heparin-Induced Thrombocytopenia

Feature	Details
Thrombocytopenia	Platelet count of 100,000/μl or less or a decrease in platelet count of 50% or more
Timing	Platelet count falls 5 to 10 days after starting heparin
Type of heparin	More common with unfractionated heparin than LMWH
Type of patient	More common in surgical patients than medical patients; more common in women than in men
Thrombosis	Venous thrombosis more common than arterial thrombosis

thromboembolism have reduced survival compared with those without this complication.[158] Patients with brain tumors, pancreatic cancer, and advanced ovarian, lung, gastrointestinal tract, or prostate cancer have particularly high rates of venous thromboembolism.[159] Treatment with chemotherapy, hormonal therapy, and biologic agents, such as erythropoietin and antiangiogenic drugs, further increases the risk for venous thromboembolism.

The pathogenesis of thrombosis in cancer patients is multifactorial in origin and represents a complex interplay among the tumor, patient characteristics, and the host hemostatic system. Tumor cells often express tissue factor or other procoagulants that can initiate coagulation.[160,161] In addition to its role in coagulation, tissue factor also acts as a cell-signaling molecule that promotes tumor proliferation and spread.

Patient factors that contribute to venous thromboembolism include immobility and venous stasis secondary to extrinsic compression of major veins by tumor. Surgical procedures, indwelling central venous catheters, and chemotherapy can produce vessel wall injury.[162] In addition, tamoxifen, selective estrogen receptor modulators (SERM), L-asparaginase, and other drugs may induce an acquired hypercoagulable state by reducing the levels of natural anticoagulant proteins.[163]

L-asparaginase and combination chemotherapeutic regimens, such as breast cancer regimens of cyclophosphamide, methotrexate, and 5-fluorouracil[164] increase the risk for thrombosis. The incidence of thromboembolic events in children receiving L-asparaginase for treatment of acute lymphocytic leukemia ranges from 1.1% to 36.7%, depending on whether or not catheter-related events are included; the overall mean is 3.2%.[165] The mechanism likely involves decreased synthesis of antithrombin, protein C, and protein S, in addition to the retention of antithrombin within the endoplasmic reticulum.[33] Concomitant administration of steroids increases the risk for thrombosis,[165] and age seems to be an important risk factor; older children demonstrate a more marked decrease in anticoagulant and fibrinolytic proteins than younger children, as well as a slower recovery to normal.[166]

Patients with multiple myeloma and other plasma cell dyscrasias are at increased risk for arterial and venous thrombosis. The reason for this is unclear, but may include acquired activated protein C resistance, elevated levels of factor VIII and/or von Willebrand factor, and the influence of the paraprotein on blood viscosity and fibrinolysis.[167,168] Patients treated with thalidomide or lenalidomide are at high risk for venous thromboembolism,[169] particularly when these drugs are given in combination with dexamethasone.[170] Several thromboprophylaxis regimens have been investigated in an attempt to mitigate this risk, including aspirin, LMWH, fixed low-dose warfarin, and therapeutic doses of warfarin, but the optimal regimen remains elusive. A recent randomized clinical trial compared aspirin, low-dose warfarin and LMWH in myeloma patients who were receiving combination therapy with lenalidomide, steroids, and melphalan. Although the results suggested that aspirin and fixed low-dose warfarin were as effective as LMWH for reducing serious venous or arterial thromboembolic events and sudden death,[171] additional studies are needed to confirm these findings.

A proportion of patients who present with unprovoked venous thromboembolism have occult cancer. This observation has prompted some experts to recommend extensive screening for cancer in such patients. Any benefits of this approach, however, are offset by potential harms. These include procedure-related morbidity, the psychologic impact of false-positive tests and the cost of screening. Furthermore, early detection of cancer is only of benefit if there is potentially curative therapy. To date, only screening for breast, cervical, and possibly colon cancer have been shown to reduce mortality.[172]

Small studies comparing extensive cancer screening with no screening in patients with unprovoked venous thromboembolism have yet to demonstrate that extensive screening reduces cancer-related mortality. Therefore it is difficult to recommend extensive screening at this time.[5] Instead, a careful history should be taken to identify any symptoms suggestive of underlying cancer. If such symptoms are present, further investigation is warranted. If there are no symptoms suggestive of underlying cancer, patients should be encouraged to undergo age-appropriate screening tests for breast, cervical, colon, or prostate cancer.

Myeloproliferative Disorders

The most common Philadelphia chromosome-negative (Ph-neg) myeloproliferative disorders, essential thrombocythemia (ET) and polycythemia vera (PV), are associated with an increased risk for thrombosis, especially arterial thrombosis, and venous thrombosis affecting the splanchnic vessels, including the hepatic and portal veins, which can lead to the Budd-Chiari syndrome, or the mesenteric veins. Thrombosis involving the microcirculation is common in patients with ET, and patients may complain of erythromelalgia, characterized by burning pain, redness and swelling of the fingers and toes, transient visual defects, or recurrent headache. Although ET and PV may evolve to myelofibrosis or transform into acute myeloid leukemia, fatal cardiovascular events are a leading cause of mortality.[173] The reported cumulative risk for thrombosis ranges from 2.5% to 5.0% per patient-year in PV and from 1.9% to 3% per patient-year in ET, depending on the patient risk category.[173-175] Age over 60 years and a previous history of thrombosis are risk factors for serious thrombosis, whereas usual cardiovascular risk factors, such as hypertension, diabetes, dyslipidemia and smoking, may place patients at intermediate risk.

The pathogenesis of thrombosis in patients with myeloproliferative disorders is multifactorial in origin and includes leukocytosis,[176] leukocyte activation, rheologic abnormalities due to raised red cell mass in PV, abnormal platelet function, and a prothrombotic endothelial phenotype.[177]

An acquired point mutation in the Janus kinase 2 gene (JAK2 G1849T) is found in up to 95% of patients with Ph-neg PV and in 50% to 60% of those with ET.[178-182] The JAK2 gene encodes a cytoplasmic tyrosine kinase that is critical for signaling between type 1 cytokine receptors and intracellular proliferation mechanisms. Currently, it is uncertain whether patients with the JAK2 mutation are at higher risk for thrombosis.[183,184] Clinical observations, supported by laboratory studies, suggest an association between the JAK2 mutation and increased leukocyte and platelet activation, as well as a correlation between the burden of the mutant allele and thrombin generation or activated protein C resistance secondary to a reduction in free protein S levels has been demonstrated in patients with ET and PV.[185] Overall, there is little to support routine JAK2 screening unless splenomegaly or an elevated hemoglobin, white blood cell, and/or platelet count raises the possibility of an underlying myeloproliferative disorder. However, it may be justifiable to check for the JAK2 mutation in patients with unexplained splanchnic or mesenteric vein thrombosis, even in the absence of evidence of these findings.[186]

Current management of PV and ET is aimed at prevention of major cardiovascular events and is based on the patient's risk category. Low-risk patients with PV are managed with phlebotomy, whereas high-risk patients are given cytoreductive therapy. Low-dose aspirin (70-100 mg daily) is recommended for all PV patients regardless of risk category, and such therapy is highly effective for treatment of the microcirculatory disturbances in patients with ET.

Paroxysmal Nocturnal Hemoglobinuria

A rare, but serious disorder, paroxysmal nocturnal hemoglobinuria (PNH) is associated with intravascular hemolysis and cytopenia.[187,188] PNH is caused by the clonal expansion of a hematopoietic stem cell that has a somatic mutation in the X-linked PIGA gene, which encodes cell surface proteins that serve as phosphatidylinositol anchors.[189] Patients with PNH may have life-threatening thrombosis that can be difficult to recognize when it affects the splanchnic or cerebral veins. Severe persistent abdominal pain or headache in patients with PNH should prompt appropriate radiologic

investigations to exclude thrombosis.[188] Although patients with PNH who have documented thrombosis should be treated with anticoagulants, phlebotomy, cytoreductive therapy, and eculizumab are important adjunctive measures to reduce the risk for recurrence.[188]

Pregnancy

Pregnancy is an independent risk factor for venous thromboembolism, and the risk for venous thromboembolism in pregnant women is five- to sixfold higher than that in age-matched nonpregnant women.[7] About 1 in 1000 pregnancies are complicated by venous thromboembolism, and about 1 in 1000 women develop venous thromboembolism in the postpartum period.[190,191] Thus venous thromboembolic disease is the leading cause of maternal morbidity and mortality and is estimated to account for 12% of fatalities in pregnancy.[192-194]

The individual risk for venous thromboembolism in pregnancy and the puerperium, defined as the 6-week period after delivery, is influenced by patient-related factors. These factors include age over 35 years, body mass index over 29, Cesarean delivery, prolonged immobilization, obesity, and thrombophilia or family history of venous thromboembolism.[190,195,196] Multiparity, ovarian hyperstimulation, and a past history of venous thromboembolism[197] are other risk factors.

Over 90% of deep vein thrombosis in pregnancy occurs in the left leg because the enlarged uterus further compresses the left iliac vein by placing pressure on the overlying right iliac and ovarian arteries.[198,199] A similar mechanism likely explains the isolated left iliofemoral thrombosis that can occur in pregnancy.

Hypercoagulability of the blood occurs in pregnancy and reflects a combination of venous stasis and changes in the hemostatic system. The enlarging uterus reduces venous blood flow from the lower extremities. This is not the only mechanism responsible for venous stasis because blood flow from the lower extremities begins to decrease by the end of the first trimester, likely reflecting hormonally induced venous dilatation. Systemic factors also contribute to hypercoagulability. Thus the levels of circulating procoagulant proteins increase in the third trimester of pregnancy. These include factor VIII, fibrinogen, and von Willebrand protein, among others.[200,201] Coincidentally, suppression of natural anticoagulant pathways and decreased fibrinolytic activity occur. Thus there is an acquired resistance to activated protein C that is related, at least in part, to reduced levels of free protein S.[76,202,203] The net effect of these changes is enhanced thrombin generation, in addition to release of tissue factor from the uteroplacental circulation, as evidenced by elevated levels of prothrombin fragments and thrombin/antithrombin complexes.[204,205] Platelet activation and increased platelet turnover occur, and mild thrombocytopenia, likely secondary to consumption, occurs in 8.3% of women at term.[206] The altered levels of hemostatic proteins normalize 4 to 6 weeks after delivery.

About half of the episodes of venous thromboembolism in pregnancy occur in women with thrombophilia.[207,208] The risk for venous thromboembolism in women with thrombophilic defects depends on the type of abnormality and the presence of other risk factors.[209] The risk appears to be highest in women with antithrombin, protein C, or protein S deficiency and lower in those with heterozygosity for the factor V_{Leiden} or FIIG20210A mutations.[210-212] In general, the daily risk for venous thromboembolism in these women is higher in the postpartum period than it is during pregnancy.[213,214] The risk during pregnancy is similar in all three trimesters.[209] Therefore, if thromboprophylaxis is given during pregnancy, it must be administered throughout the pregnancy and continued for at least 6 weeks postpartum.[215]

Assisted Conception and Ovarian Hyperstimulation Syndrome

The overall risk for venous thrombosis in women undergoing ovarian hyperstimulation is small (estimated as 0.1% per treatment cycle).[216] Often, thrombosis affects veins of the upper extremities or the jugular veins; the explanation for this phenomenon remains unclear. Thrombophilia testing is not routinely recommended in women undergoing ovarian stimulation as its predictive value is low.

Hormonal Therapy

Oral contraceptives, estrogen replacement therapy,[217] and SERM are all associated with an increased risk for thrombosis.[217,218] The relatively high risk for venous thromboembolism associated with early oral contraceptives prompted development of low-dose formulations containing reduced doses of estrogen and progestin. Currently available low-estrogen combination oral contraceptives contain 20 to 50 μg of ethinylestradiol and one of several different progestins. Even these low-dose combination contraceptives are associated with a three- to fourfold increased risk for venous thromboembolism compared with the risk in nonusers. In absolute terms, this translates to an incidence of 3 to 4 per 10,000 compared with 5 to 10 per 100,000 in nonusers of reproductive age.[219]

Although smoking increases the risk for myocardial infarction and stroke in women taking oral contraceptives, it is unclear whether smoking affects the risk for venous thromboembolism.[220] In contrast, obesity increases the risk for both arterial and venous thrombosis.[221] The risk for venous thromboembolism is highest during the first year of oral contraceptive use and persists only for the duration of use.[222,223]

Case-control studies suggest that the risk for venous thromboembolism is 20- to 30-fold higher in women with inherited thrombophilia who use oral contraceptives than the risk for nonusers with thrombophilia or users without these defects.[219,224-226] Despite the increased risk, however, routine screening for thrombophilia is not indicated in women considering the use of oral contraceptives. Based on the estimated incidence and case fatality rate of thrombotic events, it is estimated that 400,000 women would need to be screened to detect 20,000 carriers of factor V_{Leiden}. Oral contraceptives would need to be withheld in all of these women to prevent a single death.[227] For less prevalent thrombophilic defects, even large numbers of women would need to be screened. Based on these considerations, routine screening cannot be recommended.

Oral contraceptive pills may cause prothrombotic side effects by inducing modest increases in levels of procoagulant factors (such as factors VII, VIII, X, prothrombin, and fibrinogen) and decreases in the levels of anticoagulant proteins (such as antithrombin and protein S). Acquired APC resistance is an almost universal finding in women taking oral contraceptives; the clinical significance of this phenomenon is uncertain.

In recent years, mounting evidence suggests that hormonal replacement therapy with conjugated equine estrogen (with or without a progestin) increases the risk for myocardial infarction, ischemic stroke, and venous thrombosis. Carriers of the factor V Leiden mutation receiving hormone replacement therapy have a significantly increased risk for venous thromboembolism.[162,228] Data from the Heart and Estrogen Replacement Study (HERS) and the Estrogen Replacement and Atherosclerosis Trial indicate that heterozygous carriers of the factor V_{Leiden} mutation who were taking hormone replacement therapy had a 14-fold higher risk for venous thromboembolism compared with noncarriers receiving placebo.[229,230] Based on this information, the use of hormone replacement therapy has markedly decreased.

SERMs are estrogen-like compounds. The prototypical SERM is tamoxifen, which serves as an estrogen antagonist in the breast, but has an estrogen agonist in other tissues, such as bone and uterus.[231] Like estrogens, tamoxifen increases the risk for venous thromboembolism three- to fourfold.[232] The risk is higher in postmenopausal women, particularly those also receiving systemic combination chemotherapy.[163]

Aromatase inhibitors are replacing tamoxifen for treatment of estrogen receptor–positive breast cancer. These newer agents are associated with a lower risk for venous thromboembolism than is tamoxifen.[233] Raloxifene, a SERM used to prevent osteoporosis, increases the

risk for venous thromboembolism threefold compared with placebo.[234] Therefore this agent is contraindicated for prevention of osteoporosis in women with a prior history of venous thromboembolism.[214]

Prior History of Venous Thromboembolism

A history of previous venous thromboembolism places patients at risk for recurrence.[235,236] Those with unprovoked venous thromboembolism have a particularly high risk for recurrence when anticoagulant treatment is stopped.[237] Their risk for recurrence is about 10% at 1 year and 30% at 5 years. This risk occurs regardless of whether or not there is an underlying thrombophilic defect, such as factor V_{Leiden} or the FIIG20210A mutation.

The risk for recurrent venous thromboembolism is lower in patients whose incident event occurred in association with a well-recognized and transient risk factor, such as major surgery or prolonged immobilization. These patients have a risk for recurrence of about 4% at 1 year and 10% at 5 years. Patients whose initial venous thromboembolic event was associated with minor risk factors, such as oral contraceptive use or following a long distance flight, likely have an intermediate risk for recurrence.[238,239] Patients at highest risk for recurrence are those homozygous for factor V_{Leiden} or the FIIG20210A mutation and those with antiphospholipid antibody syndrome, advanced malignancy, or inherited deficiencies of antithrombin, protein C, or protein S. These patients' risk for recurrence is likely to be 15% at 1 year and up to 50% at 5 years.[95-97]

COMBINED INHERITED AND ACQUIRED HYPERCOAGULABLE STATES

Hyperhomocysteinemia is the prototypical hypercoagulable state that occurs due to a combination of inherited and acquired factors.[240,241] Homocysteine is an intermediate sulfur-containing amino acid that acts as a methyl group donor during the metabolism of methionine, an essential amino acid derived from the diet. The interconversion of methionine and homocysteine depends on the availability of 5-methyltetrahydrofolate, a methyl group donor, vitamin B_{12} and folate, cofactors in the interconversion, and the enzyme methionine synthase.[242] Increased levels of homocysteine can be the result of increased production or reduced metabolism. Severe hyperhomocysteinemia and cysteinuria are rare and are usually caused by deficiency in the enzyme, cystathione β-synthetase.[243] More common is mild to moderate hyperhomocysteinemia. This can be caused by genetic mutations in methyltetrahydrofolate reductase (MTHFR) when they are accompanied by nutritional deficiency of folate, vitamin B_{12}, or vitamin B_6.[244] Common polymorphisms in MTHFR, C677T and A1298C, are associated with reduced enzymatic activity and increased thermolability. The cofactor requirements are therefore increased with these mutations.[2] Hyperhomocysteinemia also can be associated with certain drugs, such as methotrexate, theophylline, cyclosporine, and most anticonvulsants, as well as some chronic diseases, such as end-stage renal disease, severe hepatic dysfunction, and hypothyroidism.[245]

A fasting serum homocysteine level over 15 mmol/L is considered elevated. Although elevated levels were a common finding, routine fortification of flour with folic acid has resulted in lower homocysteine levels in the general population.[246,247] Elevated serum levels of homocysteine have been associated with an increased risk for arterial thrombosis (myocardial infarction, stroke, and peripheral arterial disease) and venous thromboembolism.[245,248]

Elevated levels of homocysteine can be reduced by administration of folate with vitamin B_{12} and vitamin B_6.[249] Recent randomized trials, however, have shown that reduction of homocysteine levels with vitamin therapy does not reduce the risk for recurrent cardiovascular events in patients with coronary artery disease or stroke,[250] nor does it lower the risk for recurrent venous thromboembolism. Based on these negative trials and the declining incidence of hyperhomocysteinemia, the enthusiasm for screening for hyperhomocysteinemia has rapidly declined.

CLINICAL EVALUATION OF PATIENTS WITH HYPERCOAGULABLE STATES

A carefully taken history is essential to evaluate a patient with a history of thrombosis. The patient's age at the time of thrombosis, the location of the thrombosis and results of objective diagnostic tests should be recorded. A historical record of previous thromboses and sites, and potential risk factors, such as recent surgery, trauma, prolonged immobility, pregnancy, or estrogen use should be noted. A family history of thrombosis, especially in first-degree relatives may point to a heritable thrombophilic defect; systemic symptoms, such as anorexia, weight loss, change in bowel habits, or gastrointestinal bleeding may suggest an underlying malignant condition.

A full physical examination should be conducted with attention to abdominal or pelvic masses, lymphadenopathy, and skin changes such as skin necrosis and livedo reticularis. Basic investigations are necessary to exclude acquired causes of thrombosis and to assess the patient's general health and tolerance to anticoagulation (see box on Routine Investigations to Evaluate a Patient With [Venous] Thrombosis).

THROMBOPHILIA SCREENING

In the past, the indications for thrombophilia screening were somewhat controversial,[251,252] and the implications of such tests were often misinterpreted.[253] It is now apparent that testing for heritable thrombophilia does not predict the likelihood of recurrence in unselected

Routine Investigations to Evaluate a Patient With (Venous) Thrombosis

Test	*Abnormality*	*Diagnostic Information*
Complete blood count	Elevated hematocrit Increased white count Increased platelet count Leukopenia Thrombocytopenia	Myeloproliferative disorder (e.g., essential thrombocythemia, polycythemia vera); may be found in paroxysmal nocturnal hemoglobinuria; if associated with heparin administration, consider heparin-induced thrombocytopenia
Blood film	Leukoerythroblastic film	Underlying neoplasm invading bone marrow
Liver function tests	Abnormal tests	May point to malignancy
Renal function	Impaired renal function	Assess prior to anticoagulation with heparin or LMWH
Urinalysis	Proteinuria	Nephrotic syndrome; may be associated with venous thromboembolism or renal vein thrombosis
PT and aPTT	Prolonged PT and aPTT	To enable safe anticoagulation to proceed if required Need to exclude lupus anticoagulant

patients with symptomatic venous thrombosis.[254,255] For patients with a first episode of venous thromboembolism, thrombophilia screening is indicated only if the results influence the duration of treatment or have an impact on family counseling regarding use of estrogen-containing compounds.[53] It is reasonable to screen patients whose first episode of thrombosis occurred before the age of 40 years, patients with thrombosis in an unusual site,[256] such as cerebral or mesenteric veins, and those with two or more first-degree relatives with unprovoked thrombosis. Women with a previous unprovoked episode of thrombosis and those who develop thrombosis during pregnancy or in association with estrogen treatment qualify for thromboprophylaxis on the basis of clinical history alone, but it is not unreasonable to perform a thrombophilia screen in such situations. It also is reasonable to screen women with a history of more than one second-trimester pregnancy loss or intrauterine death.[7] Neonates and children with purpura fulminans should be urgently tested for protein C or S deficiency, as should adults who develop skin necrosis in association with vitamin K antagonists[257] (see box on When to Perform a Thrombophilia Screen).

LABORATORY EVALUATION OF THROMBOPHILIA

Screening should include functional assays for antithrombin and protein C, an immunoassay for free protein S, testing for activated protein C resistance using the modified APC sensitivity ratio with DNA testing for the factor V_{Leiden} mutation if the screening test is positive, DNA testing for the FIIG20210A gene mutation, phospholipid-based clotting tests to detect a lupus anticoagulant and enzyme immunoassay for ACL[5] (see box on Essential Tests for Thrombophilia Screening). The benefits and potential harms of thrombophilia testing should always be discussed in advance with the patient because the psychologic impact of knowing that they are a carrier of a genetic defect is one of the disadvantages of testing,[54,258] and test results may also impact on the cost of life insurance.

When to Perform a Thrombophilia Screen

Clinical Scenario

- First episode of unprovoked venous thromboembolism in individuals younger than 40 years of age
- Thrombosis in an unusual site (e.g., cerebral or mesenteric thrombosis)
- Two or more first-degree relatives with unprovoked thrombosis
- Females with a history of more than one second-trimester pregnancy loss or intrauterine death

Essential Tests for Thrombophilia Screening

Basic coagulation screen
- International Normalized Ratio (INR): to exclude warfarin effect—warfarin will lower protein C and S levels
- Activated partial thromboplastin time (aPTT): to exclude heparin effect—heparin will lower antithrombin levels

Functional assay for antithrombin: (with heparin to detect type II defects)
Functional assay for protein C
Functional assay for protein S: (immune assays for total and free protein S)
APC resistance assay: with genetic test for factor V_{Leiden} for confirmation of abnormal results
Genetic test for FIIG20210A gene mutation

The timing of thrombophilia screening is critical. Levels of natural anticoagulants may be lower at the time of an acute thrombotic event; additionally, heparin can reduce the level of antithrombin, while vitamin K antagonists, such as warfarin, reduce the levels of protein C and protein S. Therefore testing is best performed after the acute event and when anticoagulant treatment has stopped. During pregnancy, protein S levels fall, which complicates the diagnosis of protein S deficiency. The investigation of other family members may be helpful to exclude an acquired cause.

MANAGEMENT OF THROMBOSIS IN PATIENTS WITH HYPERCOAGULABLE STATES

Thrombosis treatment is usually divided into two overlapping stages, initial treatment and extended therapy. The impact of hypercoagulable states on these two stages is discussed separately as is their impact on duration of anticoagulant therapy and recommendations for prevention of recurrence.

Initial Treatment

With few exceptions, management of initial thrombotic events in patients with hypercoagulable states is no different from the management of these events in patients without underlying hypercoagulable disorders.[101] The exceptions are purpura fulminans in newborns with homozygous protein C or protein S deficiency, warfarin-induced skin necrosis, and thrombosis in patients with severe antithrombin deficiency. Newborns with purpura fulminans require protein C or protein S concentrates or sufficient amounts of plasma to increase the levels of protein C or protein S.[259,260]

Patients with severe antithrombin deficiency can usually be managed with low-molecular-weight-heparin (LMWH) or unfractionated heparin, although some patients may require considerably higher doses to achieve therapeutic anticoagulation. Some individuals may require antithrombin concentrates to increase plasma levels of antithrombin to a point where heparin or LMWH can be used for treatment.[113,261] Antithrombin concentrates are commercially available in plasma-derived and recombinant forms. The aim of treatment with antithrombin concentrate is to initially increase antithrombin activity to greater than 120% of the normal level (based on an expected 1.4% increase above baseline activity level per IU/kg of antithrombin administered) and to then maintain antithrombin activity at over 80% of the normal level.[262] Plasma antithrombin levels need to be monitored to ensure that levels over 80% are maintained; antithrombin has a half-life of 2 to 4 days. A recombinant human antithrombin concentrate produced in the milk of transgenic goats has recently become available; due to differences in glycosylation, transgenic antithrombin has a shorter half-life of 11 hours and a fourfold higher affinity for heparin.[263]

The management of acute venous thromboembolism in patients with APS is similar to that in other patients. However, monitoring treatment with heparin or vitamin K antagonists can be problematic because the aPTT or INR may be prolonged at baseline. Under these circumstances, heparin can be monitored using an anti-Xa assay. Alternatively, LMWH or fondaparinux can be used in place of heparin because these agents do not require coagulation monitoring. In asymptomatic subjects with laboratory evidence of ACL or LA, but no history of venous or arterial thrombosis, appropriate thromboprophylaxis should be given at time of thrombotic challenge, such as major surgical procedures, prolonged immobilization, or pregnancy and the puerperium. There is no indication for primary preventive treatment with anticoagulants or antiplatelet agents in such individuals.

Extended Therapy

Extended treatment of thrombosis in patients with hypercoagulable states is similar to that of patients without these underlying disorders. Caution is needed when starting patients with protein C or protein

S deficiency on warfarin or other vitamin K antagonists to prevent skin necrosis.[264] Warfarin should not be started in these patients until therapeutic anticoagulation has been fully achieved with heparin or LMWH. Once started, low doses of warfarin should be given to prevent precipitous decreases in the levels of protein C or protein S; the heparin or LMWH should only be stopped when the INR has been therapeutic for at least 2 consecutive days.

Recent randomized trials have shown that usual-intensity warfarin (target INR of 2.0 to 3.0) is as effective as higher-intensity warfarin in patients with antiphospholipid antibody syndrome. The risk for major bleeding is lower with usual-intensity warfarin than it is with higher-intensity regimens.[265,266] A target INR of 2.5 with an INR range from 2.0 to 3.0 is appropriate for patients with other hypercoagulable states as well.[267]

Patients with thrombosis who have a history of metastatic cancer may do better with extended treatment with LMWH. Randomized clinical trials have shown that, compared with warfarin, LMWH reduces the risk for recurrent venous thromboembolism without increasing bleeding.[268] Furthermore, LMWH simplifies treatment because it can be given subcutaneously once-daily without coagulation monitoring. The drug can be held before invasive procedures, and the dose may be reduced if thrombocytopenia is present. The major drawbacks of LMWH are cost and its requirement for parenteral administration, although the drug has been shown to be cost-effective in patients at high risk for recurrent venous thromboembolism (see box on Clinical Scenarios That Merit Long-Term Anticoagulation).

In patients with APS, warfarin is effective for prevention of recurrent thrombosis, and randomized clinical trials have demonstrated that a target INR of 2 to 3 is as effective as an INR of 3 to 4 in prevention of recurrent venous thromboembolism.[269,270] If the baseline INR is prolonged because of LA, vitamin K antagonists can be monitored by following the levels of factor X and titrating the dose of warfarin to maintain factor X levels less than 25% of normal; extended treatment with LMWH is another option.

Duration of Treatment

The presence of a hypercoagulable state has no influence on the duration of anticoagulant treatment in patients whose venous thromboembolic event occurred in the setting of a well-recognized and transient risk factor, such as major surgery or prolonged immobilization due to medical illness. These patients are treated with anticoagulants for at least 3 months.[271] For those with unprovoked venous thromboembolism, a minimum of 3 months of anticoagulation treatment is recommended, but most patients are given long-term treatment provided that they are not at high risk for bleeding.[237,272] Heterozygosity for factor V_{Leiden} or the FIIG20210A mutation does not influence the risk for recurrence. In contrast, patients with deficiency of antithrombin, protein C, or protein S or those homozygous for factor V_{Leiden} or the FIIG20210A mutation appear to be at higher risk for recurrence and likely should receive longer-term anticoagulation treatment.[273-275] Likewise, patients with APS with a persistent ACL or LA are also at high risk for recurrence and require long-term treatment.[132]

The decision to continue anticoagulation indefinitely requires consideration of the site and severity of the first episode of venous thromboembolism, information on whether or not the event was provoked, consideration of other risk factors, and an assessment of the risk for anticoagulant-related bleeding.[257] The decision should also take into account patient adherence and patient preferences. Commonly cited criteria for indefinite anticoagulation include the following: two or more unprovoked venous thrombotic events within a relatively short space of time (i.e., less than 2 years); one unprovoked event in an individual with antithrombin, protein C or S deficiency, persistently positive LA and/or ACL, or active cancer; a single unprovoked event in an individual with combined heterozygosity or homozygosity for factor V_{Leiden} or the prothrombin gene mutation; and a single unprovoked severe pulmonary embolism.

Clinical Scenarios That Merit Long-Term Anticoagulation*

- Two or more unprovoked venous thrombotic events in less than 2 years, or within a relatively short space of time
- A single unprovoked thrombosis in an individual with antithrombin deficiency, APS, dual heterozygosity for the factor V_{Leiden} and FIIG20210A gene mutations, or homozygosity for these mutations
- A single unprovoked massive or submassive pulmonary embolism
- An episode of venous thrombosis in a patient with active malignancy

*Note: Each clinical scenario requires an individual assessment of the balance between the risks for recurrent thrombosis and major hemorrhage and should consider patient preference.

Treatment and Prevention of Thrombosis During Pregnancy

Thrombophilic disorders have no influence on the treatment of venous thrombosis during pregnancy. These women require therapeutic doses of subcutaneous heparin, LMWH, or fondaparinux throughout pregnancy.[215,276] Heparin is given once daily with the dose titrated to achieve a therapeutic midinterval aPTT. LMWH can be given once or twice daily in a weight-adjusted fashion.[209] Monitoring with anti–factor Xa levels is recommended, particularly in the third trimester. Fondaparinux is given once daily. It is uncertain whether monitoring is required. After delivery, LMWH or warfarin should be given for at least 4 to 6 weeks. In total, treatment should be given for 6 months from the time of diagnosis. Warfarin and LMWH can be safely administered in nursing mothers, with no detectable anticoagulant effect in breast milk.[135]

Women with a past history of unprovoked or recurrent venous thromboembolism, those homozygous for factor V_{Leiden} or the FIIG20210A mutation, and those with deficiencies of antithrombin, protein C, or protein S should receive antepartum prophylaxis with heparin or LMWH.[215] Postpartum, LMWH or warfarin should be given for 4 to 6 weeks.[277] Postpartum treatment with LMWH or warfarin for 4 to 6 weeks is likely adequate for women with a history of venous thrombosis secondary to a well-defined risk factor.[278] Prophylaxis during pregnancy, as well as postpartum, should be considered for women who developed venous thromboembolism after taking oral contraceptives particularly if they have underlying thrombophilia. Women with thrombophilic defects and no prior history of venous thromboembolism likely do not require antepartum prophylaxis or postpartum treatment, but definitive data are lacking.[215] A summary of these recommendations is provided in Table 142-7.

Thrombophilia and Fetal Loss

About 30% of women have at least one fetal loss, and approximately 5% of women of reproductive age experience recurrent fetal loss.[279] Women with hereditary thrombophilia have a two- to fivefold increased risk for fetal loss.[280] Acquired hypercoagulable states, particularly antiphospholipid antibody syndrome, also increase the risk for fetal loss.[281-283] The use of once-daily heparin or LMWH in prophylactic doses, with or without aspirin, is often prescribed for women with recurrent fetal loss on the background of an underlying thrombophilic defect, although no adequate clinical trial assessing the efficacy of such an approach is available.[277]

CONCLUSIONS AND FUTURE DIRECTIONS

Inherited or acquired hypercoagulable states can now be identified in up to 50% of patients with venous thromboembolism thanks to an

Table 142-7 Management of Women With a History of Venous Thrombosis During Pregnancy and the Puerperium

Clinical History	Thrombophilia	Antepartum	Postpartum*
Prior VTE due to a transient risk factor	No	Surveillance	Yes
Prior VTE due to pregnancy or estrogens	Yes or no	Prophylactic heparin or LMWH	Yes
Prior idiopathic VTE	Yes or no	Prophylactic heparin or LMWH	Yes
Recurrent VTE	Yes or no	Treatment-dose heparin or LMWH	Resume long-term anticoagulation
No prior VTE	Antithrombin deficiency; homozygous FIIG20210A; or Factor V leiden; or dual heterozygosity for both mutations	Treatment-dose heparin or LMWH	Yes Consider antithrombin concentrate in antithrombin deficiency

*Postpartum prophylaxis involves a 4- to 6-week course of warfarin with the dose adjusted to achieve an INR of 2.0 to 3.0. Prophylactic doses of LMWH can be used as an alternative.

increased understanding of the regulation of coagulation. The role of these disorders in the pathogenesis of arterial thrombosis is less clear, and further research is necessary to identify those individuals vulnerable to arterial thrombosis after plaque rupture. Despite an improved ability to diagnose hypercoagulable states, the impact of this information on clinical decisions remains limited. Common congenital hypercoagulable states increase the risk for a first thrombotic episode but appear to have little impact on the risk for recurrence. Identification of biomarkers for patients at risk for recurrent thrombosis and elucidating new hypercoagulable states are goals for the future.

CHAPTER 143

ANTIPHOSPHOLIPID SYNDROME

Jacob H. Rand and Lucia R. Wolgast

The antiphospholipid (aPL) syndrome (APS) is an autoimmune thrombophilic condition that is defined by a combination of clinical and laboratory criteria. This chapter reviews the current understanding of aPL-mediated pathogenic mechanisms, diagnostic tests for the condition, its clinical manifestations, and current treatment approaches.

DEFINITION AND DIAGNOSTIC CATEGORIES

In general terms, APS can be described as an autoimmune thrombophilic condition in which patients have circulating antibodies against plasma proteins that bind to phospholipids. The formal investigational criteria for APS (often referred to as the Sydney Criteria), detailed in Table 143-1, require that patients have documented evidence of vascular thrombosis or obstetric complications attributable to placental vascular insufficiency. The latter include otherwise unexplained recurrent miscarriages, intrauterine growth restriction, intrauterine fetal demise, preeclampsia or toxemia, placental abruption, and preterm labor. The laboratory criteria require persistent abnormality of one or more of the aPL assays (i.e., at least two abnormal measurements at least 12 weeks apart), which include elevated anticardiolipin (aCL) immunoglobulin G (IgG) or IgM antibodies, anti–β_2-glycoprotein I (anti-β_2GPI) IgG or IgM antibodies, or a lupus anticoagulant (LA). As described in this chapter, the diagnosis of APS in a patient with thrombosis may have an impact on the duration and intensity of anticoagulant treatment.

It is important for readers to understand that these criteria were not designed as requirements for the clinical diagnosis of APS. Rather, the intent was to provide a uniformly rigorous definition of APS for standardization of research on the disorder. In clinical practice, some patients may be appropriately diagnosed with presumptive APS without meeting the strict investigational criteria. Occasional patients may even have negative test results on aPL assays but have typical clinical manifestations of the disorder, a situation referred to as *seronegative APS* (SNAPS).

Patients with APS may also have clinical manifestations that have been associated with aPL antibodies but were not included in the clinical criteria. These "noncriteria manifestations" include thrombocytopenia, livedo reticularis, skin ulcers, nephropathy, migraine, cognitive defects, diffuse alveolar hemorrhage and valvular heart disease (Libman-Sachs endocarditis). Some patients with APS may also test positive for "noncriteria" clinical laboratory tests (described later) that have not been included by consensus panels as diagnostic criteria for the disorder.

At the present time, APS may be divided into the following subcategories: (1) primary APS is "stand-alone" APS in the absence of systemic lupus erythematosus (SLE); (2) secondary APS occurs in the presence of SLE; (3) SNAPS includes patients who test entirely negative for the disorder but are nevertheless suspected of having it on clinical grounds; and (4) catastrophic APS (CAPS), which manifests as disseminated thrombosis in large and small vessels with resulting multiorgan failure (Table 143-2).

ANTIGENIC SPECIFICITIES OF ANTIPHOSPHOLIPID ANTIBODIES

β_2Glycoprotein I

β_2-Glycoprotein I, a 50-kd glycoprotein member of the complement control protein (CCP) superfamily, is believed to be a major antigenic target for aPL antibodies. The protein consists of five homologous CCP domains, each consisting of about 60 amino acids, with a fifth domain that includes a phospholipid binding site near the NH_2-terminal of the protein (Fig. 143-1). Recently, it has been reported that the protein undergoes a conformational change when it binds to membranes. Transmission electron microscopy analysis of negatively stained β_2GPI molecules indicates that the free unbound protein has a circular confirmation that is caused by the affinity of its COOH-terminal domain (domain V) for the NH_2-terminal domain (domain I); when membrane bound, the protein assumes an open "fishhook" conformation in which the portion of domain I that is inaccessible in the coiled fishhook conformation becomes exposed for recognition by autoantibodies (see Fig. 143-1). This domain I epitope appears to be a major target for thrombogenic aPL antibodies. Binding of β_2GPI to membranes that express anionic phospholipids occurs via the affinity of cationic residues near the NH_2-terminus for anionic polar heads of phospholipids and by a hydrophobic loop that inserts into the lipid bilayer.

Several properties have been ascribed to β_2GPI, although its biologic function has not been resolved. Among these, β_2GPI binds to apoptotic cells and may aid in their phagocytosis and clearance. Recent evidence suggests that, consistent with its structure, the protein may have a complement control function. β_2GPI can also bind to oxidized low-density lipoprotein (oxLDL) and may play a role in their clearance. Recently, a new role for β_2GPI has been identified in innate immunity; the protein binds to and clears lipopolysaccharide (LPS), thereby reducing LPS binding to the Toll-like receptor 4 (TLR4), and the triggering of downstream endotoxin effects.

Although the protein has several effects on coagulation and hemostatic reactions, genetic deficiency of β_2GPI is not associated with bleeding or thrombosis in humans. Likewise, homozygous β_2GPI null mice also do not display any obvious disease phenotype. Although not yet tested, it is possible that these mice may be more susceptible to LPS challenge. The heterozygous pregnant female mice were reported to produce fewer than expected numbers of homozygous β_2GPI-null offspring, which suggested that the protein might contribute to—but not be absolutely required for—successful pregnancy. A recent study in humans suggested an atheroprotective role for the protein since elevated levels of β_2GPI-protected older (but not younger) men from myocardial infarction (MI).

All five domains of β_2GPI have been reported to be recognized by anti-β_2GPI antibodies isolated from patients. Of these, IgG antibodies directed against an epitope on domain I comprising Gly40-Arg43 has correlated with LA activity and had a strong association with thrombosis; that study also found that antibodies with heterogeneous reactivities for the other domains were not correlated with an increased risk for thrombotic complications.

Table 143-1 Sydney Investigational Criteria for the Diagnosis of the Antiphospholipid Syndrome*

CLINICAL

- Vascular thrombosis (one or more episodes of arterial, venous, or small vessel thrombosis). For histopathologic diagnosis, there should be no evidence of inflammation in the vessel wall.
- Pregnancy morbidities attributable to placental insufficiency, including: (1) three or more otherwise unexplained recurrent spontaneous miscarriages before 10 weeks of gestation; (2) one or more fetal losses after the 10th week of gestation; (3) stillbirth; and (4) episode of preeclampsia, preterm labor, placental abruption, intrauterine growth restriction, or oligohydramnios that are otherwise unexplained.

LABORATORY

- Medium- or high-titer aCL or anti-β_2GPI IgG or IgM antibody present on two or more occasions, at least 12 weeks apart, measured by standard ELISAs.
- Lupus anticoagulant in plasma on two or more occasions at least 12 weeks apart detected according to the guidelines of the ISTH SSC Subcommittee on Lupus Anticoagulants and Phospholipid-Dependent Antibodies.

Modified from Miyakis S, Lockshin MD, Atsumi T, et al: International consensus statement on an update of the classification criteria for definite antiphospholipid syndrome (APS). *Thromb Haemost* 4:295, 2006.
aCL, Anticardiolipin; *aPL,* antiphospholipid; *β_2GPI,* β_2-glycoprotein I; *ELISA,* enzyme-linked immunosorbent assay; *Ig,* immunoglobulin, *ISTH SSC,* International Society on Thrombosis and Haemostasis, Scientific and Standardization Subcommittee.
*"Definite APS" is considered to be present if at least one of the clinical criteria and one of the laboratory criteria are met.

Table 143-2 Proposed Criteria for the Classification of Catastrophic Antiphospholipid Syndrome

1. Evidence of involvement of three or more organs, systems, or tissues*
2. Development of manifestations simultaneously or in less than 1 week
3. Confirmation by histopathology of small vessel occlusion in at least one organ or tissue†
4. Laboratory confirmation of the presence of aPL antibodies (lupus anticoagulant or anticardiolipin antibodies)‡

Definite catastrophic APS
- All four criteria

Probable catastrophic APS
- All four criteria except for only two organs, systems, or tissues involvement
- All four criteria except for the absence of laboratory confirmation at least 6 weeks apart caused by the early death of a patient never previously tested for aPL before the catastrophic APS event
- Criteria 1, 2, and 4
- Criteria 1, 3, and 4 and the development of a third event in more than 1 week but less than 1 month despite anticoagulation

Modified from Asherson RA, Cevera R, de Groot PG, et al: Catastrophic antiphospholipid syndrome: International consensus statement on classification criteria and treatment guidelines. *Lupus* 12:530, 2003.
aPL, Antiphospholipid; *APS,* antiphospholipid syndrome.
*Usually, clinical evidence of vessel occlusions, confirmed by imaging techniques when appropriate. Renal involvement is defined by a 50% rise in serum creatinine, severe systemic hypertension (N180/100 mm Hg), or proteinuria (N500 mg/24 h).
†For histopathologic confirmation, significant evidence of thrombosis must be present, although in contrast to Sydney criteria, vasculitis may coexist occasionally.
‡If the patient had not been previously diagnosed as having an APS, the laboratory confirmation requires that the presence of antiphospholipid antibodies must be detected on two or more occasions at least 6 weeks apart (not necessarily at the time of the event), according to the proposed preliminary criteria for the classification of definite APS.

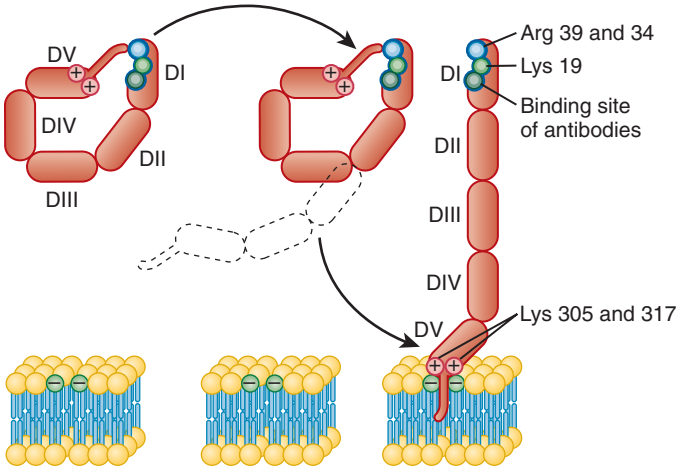

Figure 143-1 SCHEMATIC REPRESENTATIONS OF THE CONFORMATIONAL STATES OF β_2GPI. The protein circulates as a "coiled fishhook" in which the epitope on domain I (DI) is shielded by a portion of domain V (DV). Binding to phospholipid membranes via a "barb" near the carboxyterminus of DV opens the protein and exposes an immunogenic epitope near the aminoterminal portion of the molecule. *(From Rand JH: A snappy new concept for APS.* Blood *116:1193, 2010. Additional Antigenic Targets

Targets other than β_2GPI that have been identified for aPL antibodies include prothrombin, factor V, protein C, protein S, annexin A2, annexin A5, high- and low-molecular-weight (LMWH) kininogen, heparin, factor VII/VIIa, and plasmin. Recently, the cytoskeletal intermediate filament, vimentin, was also shown to be a target for aPL antibodies; in that study, about half of patients with clinical manifestations but lacking positivity for the standard aPL antibodies (i.e., patients with SNAPS) had serologic evidence for antivimentin/cardiolipin antibodies. Antibodies to lyso(bis)phosphatidic acid (LBPA), a hydrophobic isomer of phosphatidylglycerol, have also been shown to exert LA activity. Autoantibodies have also been found to bind sulfatides, acidic glycosphingolipids, which can interact with sulfatide-binding proteins such as von Willebrand factor (vWF), thrombospondin, and P-selectin.

β_2GPI appears to have both beneficial and harmful effects on the toxicity of oxLDL, which promote endothelial dysfunction and cytokine release and contribute to atherosclerosis. On the one hand, β_2GPI can bind to oxLDL to form oxLDL–β_2GPI complexes that may promote oxLDL clearance. On the other hand, recent data have indicated that binding of β_2GPI to oxLDL promotes aPL autoimmunity by facilitating dendritic cell presentation of β_2GPI epitopes to autoreactive T cells.

PATHOGENIC MECHANISMS

Several different mechanisms have been proposed to explain the thrombotic manifestations of APS (Table 143-3).

Pathogenic Effects of Anti-β_2GPI Antibodies on Endothelial Cells

Antiphospholipid antibodies can bind to, injure, or activate cultured vascular endothelial cells. Antibody binding to β_2GPI on the

Table 143-3 Proposed Pathogenic Mechanisms of Antiphospholipid Syndrome

I. Pathogenic effects of anti-β_2GPI antibodies on endothelial cells
 A. Direct injury and subsequent anti-β_2GPI binding on endothelial cells
 B. Signaling via annexin A2/TLR4/ApoER2′ inducing proadhesive prothrombotic phenotype
 C. Induction of adhesion molecules and TF on endothelial cells and cytokine release
II. Activation of platelets by aPL antibodies
 A. Activation of platelets via ApoER2′, GPIbα, or β_2GPI–platelet factor 4 interaction
 B. Interference of vWF-mediated platelet adhesion
III. Inhibition of endogenous anticoagulant and fibrinolytic mechanisms
 A. Disruption of the annexin A5 anticoagulant shield
 B. Interference with fibrinolysis via annexin A2, β_2GPI cofactor activity, autoactivation of XIIa, direct inhibition of plasmin, and increase of PAI-1
 C. Inhibition of the protein C pathway: decreased activation of protein C, barrier of APC proteolysis of factor Va and VIIIa, prevention of protein C, and EPCR binding
 D. Interference with TFPI
IV. aPL-mediated activation of complement

aPC, Activated protein C; *aPL,* antiphospholipid; *β_2GPI,* β_2-glycoprotein I; *EPCR,* endothelial cell protein C receptor; *GP,* glycoprotein; *PAI-1,* plasminogen activator inhibitor 1; *TF,* tissue factor; *TFPI,* tissue factor pathway inhibitor; *TLR4,* Toll-like receptor 4; *vWF,* von Willebrand factor.

endothelial surface can also trigger signaling cascades that promote increased expression of tissue factor (TF) and adhesion molecules (Fig. 143-2). Evidence indicates that annexin A2, which forms tetramers with S100 and is an endothelial surface receptor for tissue plasminogen activator (t-PA) and plasminogen, serves as a receptor for β_2GPI on vascular endothelium. Annexin A2 is not a transmembrane protein, and the signaling coreceptors, TLR4/TLR2 and CD14 have been implicated as triggering of the signaling cascade. In support of this aPL-mediated mechanism, a mutation in murine TLR4 that disrupts LPS binding attenuated the prothrombotic state in wild-type mice induced by aPL antibody administration.

Antiphospholipid-mediated promotion of TF expression induces trophoblast injury and fetal death in mice. In addition, TF contributes to the C5a-induced oxidative burst in neutrophils, which leads to trophoblast and fetal injury in APS. A mAb against factor B that disrupts the alternative pathway of complement activation, protects against aPL antibody–induced fetal loss in mice by preventing complexation of C3b and factor B.

Apolipoprotein E receptor 2′ (ApoER2′), a member of the LDL receptor family and a multiligand receptor with a wide tissue distribution, may also be a target for anti-β_2GPI–β_2GPI complexes that trigger TF and cell adhesion molecule expression on the endothelial surfaces (see Fig. 143-2). ApoER2′ is expressed on endothelial cells, platelets and monocytes, where it may mediate the pathogenic effects of the antibodies. Evidence from ApoER2′$^{-/-}$ knockout mice supports such a role raising the possibility that treatments that interfere with antibody binding to this receptor may be of value in APS.

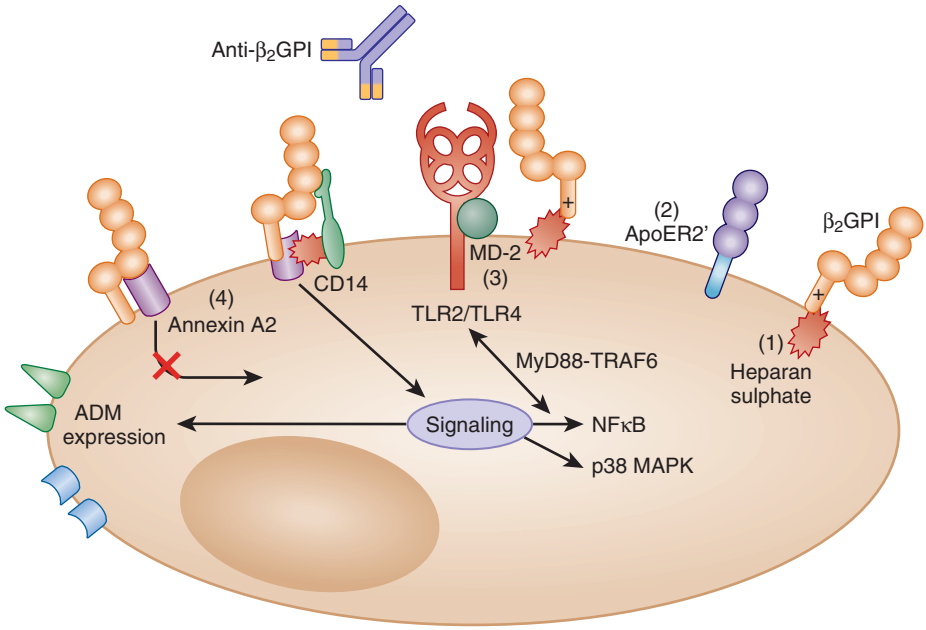

Figure 143-2 ENDOTHELIAL CELL SURFACE AND RECEPTOR ACTIVATION BY ANTI-β_2GPI–β_2GPI COMPLEXES. In this model, anti-β_2GPI–β_2GPI complexes bind to the endothelial membrane through the cationic DV of β_2GPI to a number of receptors, including (1) anionic structures, such as heparan sulfate; (2) apolipoprotein E receptor 2′ (ApoER2′); (3) Toll-like receptor 2 or 4 (TLR2/TLR4); and (4) annexin A2, to promote downstream signaling pathways involving p38 mitogen-activated protein kinase (p38 MAPK) and nuclear factor kappa-B (NFκB), leading to the upregulation of tissue factor and adhesion molecules (ADM) and a proinflammatory and prothrombotic phenotype. Annexin A2 does not have a transmembrane domain; therefore, other membrane proteins such as CD14, TLR2/TLR4, and ApoER2′, may act as accessory molecules. *β_2GPI,* β_2 glycoprotein I; *MyD88,* myeloid differentiation primary response protein MyD88; *TRAF6,* tumor necrosis factor receptor–associated factor 6. *(Adapted from Meroni PL, Borghi MO, et al: Pathogenesis of antiphospholipid syndrome: Understanding the antibodies.* Nat Rev Rheumatol *7:330, 2011.)*

Activation of Platelets by aPL Antibodies

Antiphospholipid antibodies can induce platelet activation and aggregation. The binding of β_2GPI dimers to ApoER2′ on platelets increases the sensitivity of platelets to low concentrations of agonists. Recombinant dimers of β_2GPI, which were designed to model anti-β_2GPI antibody-mediated dimerization of β_2GPI, increase platelet adhesion to collagen and thrombus formation in flow systems, effects that are abrogated by inhibiting thromboxane A2 synthesis. aPL antibodies may also interfere with the inhibitory effect of β_2GPI on the platelet–vWF interaction; this "inhibition of an inhibitor" effect may result in increased platelet adhesion.

Inhibition of Endogenous Anticoagulant and Fibrinolytic Mechanism

Antiphospholipid antibodies accelerate coagulation reactions on endothelial cells and trophoblasts by disrupting an antithrombotic shield composed of annexin A5. Annexin A5 is a potent anticoagulant protein with high affinity for phospholipid membranes that contain anionic phospholipids, specifically phosphatidylserine. The protein forms two-dimensional crystalline arrays over the phospholipid bilayers (Fig. 143-3) that render anionic phospholipids available for coagulation factor complex assembly. Annexin A5 is highly expressed by endothelial cells and on the apical membranes of placental syncytiotrophoblasts, the location where maternal blood interfaces with fetal cells. Annexin A5 binds to these cells and inhibits thrombin formation. This may explain why pregnant mice given anti–annexin A5 antibodies develop placental necrosis, fibrosis, and pregnancy loss.

Numerous studies indicate a reduction in cell surface annexin A5 in APS, including immunohistochemical analysis of placental villi in APS patients, exposure of cultured human umbilical vein endothelial cells or trophoblasts to aPL IgG, and studies with artificially reconstituted phospholipid bilayers. The reduction of cell surface annexin A5 is the result of competitive displacement by aPL IgG–β_2GPI immune complexes (see Fig. 143-3). Loss of all surface annexin A5 induces a prothrombotic phenotype.

Antiphospholipid antibodies can affect fibrinolytic mechanisms in several ways. Patients with APS have high annexin A2–directed antibodies that can interfere with t-PA or plasminogen binding to the endothelial cell surface, thereby attenuating plasmin generation. In addition, mAbs isolated from APS patients can directly inhibit plasmin activity. Finally, β_2GPI serves as a cofactor for t-PA–mediated activation of plasminogen. Consequently, aPL antibodies directed against β_2GPI can downregulate plasmin generation.

Antiphospholipid antibodies can interfere with several steps in the protein C anticoagulant pathway. These include (1) reducing the activation of protein C by the thrombomodulin–thrombin complex; (2) inhibiting the assembly of the protein C complex; (3) inhibiting the activity of protein C, or cofactor protein S; and (4) binding to factors Va and VIIIa and protecting them from proteolysis by activated protein C (APC). Some aPL antibodies can recognize protein C or protein S (or both) and may reduce their levels by accelerating their clearance. One study found an association between anti–protein C IgM and venous thrombosis. In addition, antibodies against β_2GPI may crossreact with APC and vice versa. APC resistance has been described in APS plasma and correlates with anti-β_2GPI domain I antibodies.

Autoantibodies against TF pathway inhibitor (TFPI) have also been reported in patients with APS; dysregulation of TF–factor VIIa activity may also contribute to the increased risk of thrombosis.

Antiphospholipid-Mediated Activation of Complement

Complement activation may also play a role in the APS disease process. Blockade of complement activation with a C3 convertase inhibitor or genetic deletion of C3 protects mice from the pregnancy

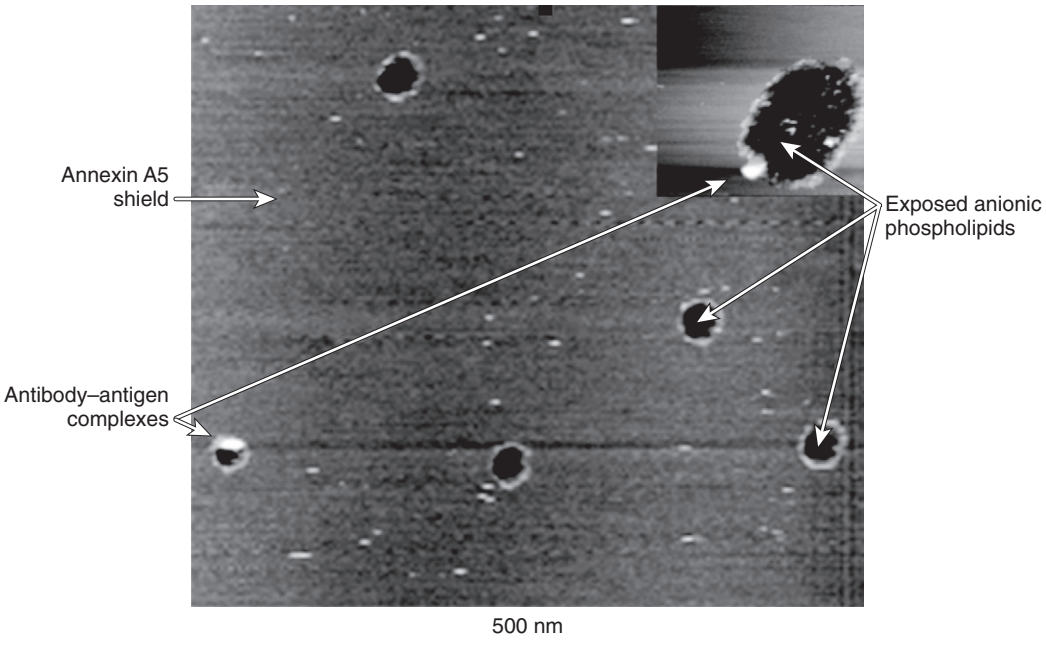

Figure 143-3 DISRUPTION OF ANNEXIN A5 SHIELD BY MONOCLONAL ANTIPHOSPHOLIPID (aPL) ANTIBODIES AND β_2 GLYCOPROTEIN I (β_2GPI). Atomic force microscopy picture showing the effect of aPL mAB IS3 on a preformed annexin A5 crystal. The figure demonstrates the smooth lipid bilayer covered by the annexin A5 crystals, disrupted by antibody–β_2GPI complexes *(white rims)* and exposing anionic phospholipids *(black holes)* to coagulation factors and accelerated coagulation. *(Adapted from Rand JH, Wu XX, Quinn AS, et al: Human monoclonal antiphospholipid antibodies disrupt the annexin A5 anticoagulant crystal shield on phospholipid bilayers: Evidence from atomic force microscopy and functional assay.* Am J Pathol *163:1193, 2003.)*

complications induced by aPL antibodies. Complement activation in APS appears to involve (1) direct aPL antibody–induced injury to endothelial cells and monocytes, which promotes cell lysis and inflammation, and (2) protease activated receptor 2 (PAR-2) signaling with upregulation of TF expression by monocytes.

Genetic, Genomic, and Proteomic Studies in Antiphospholipid Syndrome

Although familial APS is rare, genetic factors appear to influence development of aPL antibodies. In a study of seven families that included 30 individuals who met the consensus criteria for APS, the inheritance pattern of aPL antibodies appeared to be autosomal dominant. However, no specific linkages could be identified. A recent study using peripheral blood mononuclear cells isolated from aPL antibody–positive patients found a gene expression pattern that correlated with the predisposition for thrombosis. Some of these genes encoded proteins involved in thrombogenesis, including apolipoprotein E, factor X, and thromboxane. Other genes, such as hypoxia inducible factor-1 α (HIF-1α), zinc finger proteins, matrix metalloproteinase 19 (MMP19), interleukin-22 (IL-22) receptor, and hematopoietic progenitor cell antigen (CD34) precursor, had no clear connection with the disease process.

Proteomic studies also provide some insights into the pathogenesis of thrombosis in APS patients. Proteins to be differentially expressed by monocytes of APS patients with a history thrombosis, include annexin A1, annexin A2, ubiquitin Nedd8, Rho A protein, protein disulfide isomerase, and Hsp60. How these proteins might conspire to increase the thrombosis risk remains to be determined.

LABORATORY ASSAYS

Development Paths

The current assays for APS began with descriptive reports of two laboratory artifacts, the biologic false-positive (BFP) serologic test for syphilis (STS) and an unusual inhibitor to the activated partial thromboplastin time (aPTT) that was not directed against a specific coagulation factor. The immunoassays were developed in the early 1980s in an effort to quantify the BFP-STS, a laboratory phenomenon known to be associated with autoimmunity. Because cardiolipin (diphosphatidyl glycerol) is the key antigen in the STS assay, quantitative immunoassays identify and quantify antibodies in the test serum that bind to cardiolipin. Subsequent clinical studies revealed that elevated levels of aCL antibodies were associated with an increased risk of thrombosis, spontaneous abortion, and neurologic deficits. This constellation of clinical and laboratory abnormalities was recognized as a new disorder, named APS. It was subsequently discovered that the antibodies from patients with this syndrome did not directly bind to cardiolipin. Instead, the antibodies bind β_2GPI, and β_2GPI mediates the interaction with cardiolipin. It was later determined that although β_2GPI is the primary target antigen, aPL antibodies also may recognize several other phospholipid-binding proteins.

The LA assays were derived from a report by Conley and Hartmann in the early 1950s that two patients with SLE had prolonged partial thromboplastin time tests. It was these anticoagulants that were later associated with the biologic false-positive STS recurrent pregnancy loss and thrombosis. Ultimately, there was recognition that the anticoagulant reflected antibody-induced inhibition of phospholipid-dependent coagulation reactions and was part of APS. The term *lupus anticoagulant* was mistakenly coined to describe these antibodies because initial studies were done in SLE patients.

Antiphospholipid tests are inherently limited because they were not designed to measure known disease mechanisms. Nevertheless, these assays serve as surrogate reporters of thrombotic risk. Strong positivity for more than one of the aPL antibody–detection assays is indicative of an increased risk of clinical events.

Lupus Anticoagulant Tests

Overview

The various LA tests use different coagulation systems to report the inhibition of phospholipid-dependent blood coagulation reactions, These include modifications of the aPTT with LA-sensitive and LA-insensitive reagents, the kaolin clotting time (KCT), the dilute Russell viper venom time (dRVVT), the tissue thromboplastin inhibition time (TTIT), the hexagonal phase array test, and the platelet neutralization procedure. The results of LA tests may vary among laboratories; although most laboratories are able to identify plasmas containing strongly positive LA activity, they frequently disagree about samples with weak LA activity (which are missed in approximately half of the cases), and laboratories may often misdiagnose factor-deficient LA-negative plasmas as being LA positive.

Despite these limitations, the presence of LA activity is a more sensitive and specific marker for thrombosis or pregnancy loss than aCL immunoassays, both in patients with or without SLE. For example, based on a meta-analysis of studies examining the association of aPL antibodies in patients without autoimmune disease with subsequent thrombosis over a 15-year period reported mean odds ratio (OR) of 11 for LA, 3.2 for high-titer aCL antibodies and 1.6 for elevated aCL antibodies generally. In a systematic literature review, 12 of 12 studies showed significant associations between LA and thrombosis, with ORs ranging from 5.7 to 9.4. LA increased the risk of arterial and venous events to a similar extent. In contrast, only 15 of 28 studies showed significant associations between aCL antibodies and thrombosis. In the Antiphospholipid Antibodies Stroke Study (APASS), positivity for both LA and aCL antibodies, but not for aCL antibodies alone, predicted a higher risk of recurrent thrombo-occlusive events in patients with a first ischemic stroke. In the Risk of Arterial Thrombosis In relation to Oral contraceptives (RATIO) study, the presence of LA was found to be a major risk factor for arterial thrombotic events in young women, including ORs of 5.3 for MI and 43.1 for ischemic stroke. In LA-positive women taking oral contraceptives, the ORs for MI and ischemic stroke were 21.6 and 201.0, respectively. For LA-positive women who were also cigarette smokers, the ORs for MI and ischemic stroke increased to 33.7 and 87.0, respectively.

Indications for Testing

Lupus anticoagulants should not be included in routine testing panels of patients without a history of SLE, thrombosis, or pregnancy complications typical of APS. The Antiphospholipid Antibodies Subcommittee of the ISTH has prioritized the appropriateness of testing for LA into low, moderate, and high groups. The *low appropriateness group* includes elderly patients with venous or arterial thromboembolism; the *moderate group* includes asymptomatic patients with a prolonged aPTT on routine testing or young women with recurrent spontaneous early pregnancy loss and provoked venous thromboembolism (VTE); and the *high appropriateness group* includes patients with unprovoked or unexplained VTE, arterial thrombosis in young patients (<50 years of age), thrombosis in unusual sites, late pregnancy loss, and any thrombosis or pregnancy morbidity in patients with autoimmune diseases (SLE, rheumatoid arthritis, autoimmune thrombocytopenia, autoimmune hemolytic anemia). In the authors' opinion, these same guidelines may also be applied to the PL immunoassays.

The same subcommittee recommends performing two LA tests that are based on different assay principles, specifically, the dRVVT and an aPTT that uses silica as an activator and has a low phospholipid content.

Dilute Russell Viper Venom Time

The dRVVT is considered one of the most sensitive of the LA tests. The assay uses Russell viper venom (RVV) in a system containing limiting quantities of diluted rabbit brain phospholipid. RVV directly activates coagulation factor X, leading to the formation of fibrin. aPL antibodies can prolong the dRVVT by interfering with assembly of the prothrombinase complex; this prolongation is reversed by adding excess phospholipid (sometimes referred to as a "confirmatory test"). To ensure that prolongation of the clotting time is not the result of a factor deficiency, the procedure includes a mixture of patient and control plasma. Treatment with heparin, warfarin, or direct thrombin inhibitors can produce false-positive test results.

Activated Partial Thromboplastin Time

Prolonged aPTTs in otherwise healthy individuals without bleeding tendencies are most frequently caused by LAs. Different commercial aPTT reagents vary widely with respect to their sensitivities to LA, so it is important to know the characteristics of the reagent that is used. LA needs to be differentiated from inhibitors of specific coagulation factors and from anticoagulants such as heparin. Aside from specific assays to exclude the latter two possibilities, the clinician should determine whether the aPTT normalizes when an LA-insensitive aPTT reagent is used or when the assay is performed using frozen washed platelets as a source of phospholipid, a procedure referred to as the *platelet neutralization procedure*. The effects of incubation with normal plasma may be helpful to distinguish between LAs and coagulation factor inhibitors. aPTTs performed on a mixture of normal plasma with plasma containing a factor VIII inhibitor usually require incubation for 1 to 2 hours at 37° C to show prolongation, but LA-containing plasmas usually prolong the aPTT immediately after mixing with normal plasma and show no further prolongation with incubation. The clinician should be aware that, in rare patients, both types of anticoagulants (i.e., LA and specific coagulation factor inhibitors) may coexist and yield a confusing laboratory picture. LAs may cause artifactual decreases in the levels of contact activation pathway coagulation factors because those assays are based on the aPTT; these patients are sometimes misdiagnosed as having multiple coagulation factor deficiencies. This problem can be handled by repeating the coagulation factor assays after dilution of the plasma samples or by using an aPTT reagent that is insensitive to LA for coagulation factor assays.

Antiphospholipid Immunoassays

Anticardiolipin Antibody Assays

The quantities of bound aCL IgG and aCL IgM are expressed in GPL or MPL units, respectively, one unit representing the cardiolipin-binding activity of 1 μg/mL of affinity-purified aPL antibody from reference sera. Binding reflects both the titer and affinity or avidity of the antibody. aCL antibody levels in reference sera may vary among laboratories, particularly when measured with different commercial enzyme-linked immunosorbent assay (ELISA) kits.

It is important to recognize that most patients with elevated aCL antibodies encountered during the course of general screening studies do not have APS. The prevalence of positive immunoassays in the asymptomatic "normal" population has ranged from approximately 3% to nearly 20%. In a prospective study of 2132 consecutive Spanish patients with VTE, 4.1% had elevated levels of aCL antibodies (i.e., about the same prevalence as in the asymptomatic healthy population). In a group of healthy young women, 18.2% had elevated levels of aCL antibodies, and 12.8% tested LA positive. Many individuals have transient elevations in antibody levels in response to infections; these are not associated with thrombotic complications. Patients with syphilis, Lyme disease, and other infections may be misdiagnosed with APS based on elevated aCL antibody levels, particularly if they present with a stroke or arterial thrombosis.

High levels of aCL antibodies are associated with an increased risk of thrombosis. During a 10-year follow-up of patients with elevated levels of aCL antibodies, approximately 50% of those who had no clinical manifestations of APS at the outset went on to develop APS. The presence of elevated titers of aCL antibodies 6 months after an episode of VTE is a predictor of increased risk of recurrence and of death. In a systematic literature review, 15 of 28 studies showed significant associations between aCL antibodies and thrombosis. In all cases, a correlation existed between higher antibody titers and high ORs for thrombosis. Elevated levels of aCL antibodies, whether high or low titer, were significantly associated with both MI and stroke. Only high-titer aCL antibodies significantly increased the risk of deep venous thrombosis (DVT). With respect to pregnancy losses, a meta-analysis of 25 studies that examined aPL antibodies in women with recurrent fetal losses showed significant correlation; however, the highest OR was seen in those who were LA positive.

Elevated aCL antibodies of IgG or IgM isotype were reported to be significant risk factors for stroke. aPL antibodies were also reported to be an independent risk factor for stroke in young women. In the APASS, 41% of patients who were within 30 days of having an ischemic stroke tested aCL antibody positive.

Anti-β_2GPI Antibody Assay

β_2GPI is the major protein cofactor recognized by aPL antibodies. ELISAs for anti-β_2GPI antibodies are considered to be more specific but less sensitive for APS than aCL antibody assays. Although anti-β_2GPI antibodies are usually found in conjunction with abnormal aCL and antiphosphatidylserine antibodies, patients with APS may only have antibodies against β_2GPI. Despite their higher specificity for APS (98%), β_2GPI antibodies alone cannot be relied upon for the diagnosis because of their low sensitivity (40%-50%), and concurrent testing for both antibodies along with LA is advised.

In a systematic literature review, 34 of 60 studies, of which none were prospective, showed significant associations between anti-β_2GPI antibodies and thrombosis. Of 10 studies that included multivariate analysis, only two confirmed that IgG anti-β_2GPI antibodies were independent risk factors for venous thrombosis. Anti-β_2GPI antibodies were more often associated with venous than arterial events.

Multipositivity for Antiphospholipid Tests and Clinical Risk

Strong positivity for more than one of the aPL antibody assays has been correlated with an increased risk for developing clinical events in several retrospective studies and in one recent prospective study. One study showed that multipositivity for aPL antibodies, but not single positivity, was associated with antenatal and postnatal DVT. Another study of pregnant women with APS reported that patients with triple aPL antibody positivity, or previous thromboembolism appeared to have a higher probability of poor neonatal outcomes than patients with double or single aPL antibody positivity and no thrombosis history. A retrospective analysis of 162 APS patients who were positive for LA, aCL, and anti-β_2GPI antibodies reported a higher risk of recurrent thromboembolic events with a cumulative incidence of events of 44.2% after 10 years. This finding was confirmed in a recent prospective analysis of 104 triple-positive patients without a history of thrombosis or pregnancy complications who were followed for a mean of 4.5 years. The cumulative incidence for a first thrombotic event after 10 years was 37.1% (95% confidence interval [CI], 19.9%-54.3%. The annual rate of a first cardiovascular event (including VTE) was 0.4% in the patients without abnormal aPL assays, 1.36% in single aPL antibody positive carriers, and 5.3% in triple antibody positive carriers (Fig. 143-4). Male sex and the presence of other risk factors for venous thrombosis were associated with an increased risk of developing a first thrombotic event in this cohort.

A risk scale has been proposed in order to aid in the diagnosis and management of patients with APS (Table 143-4). Overall, both

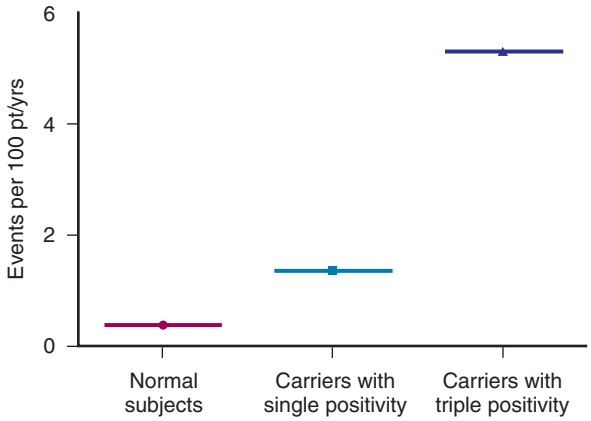

Figure 143-4 AVERAGE ANNUAL RATES OF FIRST CARDIOVASCULAR EVENTS (INCLUDING VENOUS THROMBOEMBOLISM) IN A WHITE NORMAL POPULATION IN SINGLE-POSITIVE ANTIPHOSPHOLIPID CARRIERS AND IN TRIPLE-POSITIVE CARRIERS. *(Modified from Pengo V, Ruffatti A, Legnani C, et al: Incidence of a first thromboembolic event in asymptomatic carriers of high-risk antiphospholipid antibody profile: A multicenter prospective study.* Blood *118:4714, 2011.)*

symptomatic and asymptomatic patients with triple-positive laboratory results (LA positive, aCL [IgG or IgM >40 GPL or MPL units], and anti-β_2GPI [IgG or IgM >99th percentile]) should be considered at high risk for future manifestations of APS. Those who are double positive for LA, aCL (IgG or IgM >40 GPL or MPL units) or anti-β_2GPI (IgG or IgM >99th percentile) or single positive for LA should be considered at medium risk for APS, and those with single positivity for aCL (IgG or IgM >40 GPL or MPL units) or anti-β_2GPI (IgG or IgM >99th percentile) should be considered at low risk for APS. Even in those at medium or low risk, treatment may be warranted in the presence of thrombosis or pregnancy complications or other high-risk factors.

"Noncriteria" Antiphospholipid Assays

IgA Antibodies to Cardiolipin and β_2-Glycoprotein I

The clinical utility of testing aPL antibodies of IgA isotype remains controversial. The prevalence of true positivity to aCL IgA antibodies has been reported to be very low; for example, one study of 795 patients reported positive aCL IgA in only two patients, both of

Table 143-4 Laboratory Interpretation in Antiphospholipid Syndrome Diagnosis and Treatment

Risk	Laboratory Result*	Clinical Manifestation	Treatment
High risk (OR >9)	Triple positive for LA, aCL (IgG or IgM >40 GPL or MPL), and anti-β_2GPI (IgG or IgM >99th percentile)	VTE	Long-term VKA: INR, 2.0-3.0
		Arterial thromboembolism	Stroke: Long–term VKA: INR, 2.0-3.0 plus aspirin 100 mg/day MI: Long-term VKA: INR, 2.0-3.0 plus aspirin 100 mg/day *or* Long-term VKA: INR, 3.0-4.0 MI with PCI and stent placement: Long-term VKA: INR, 2.0-3.0; aspirin 100 mg/day; and clopidogrel 75 mg/day
		Pregnant women with history of pregnancy complications or thrombotic events	UFH plus low-dose aspirin
		Asymptomatic	Consider anticoagulant prophylaxis for high-risk situations (e.g., immobilization, surgery, air travel) Consider long-term VKA; recommended to prevent thromboembolic events Consider low-dose aspirin and possible UFH for pregnant patients
Medium risk (OR, 5-9)	Double positive for LA, aCL (IgG or IgM >40 GPL or MPL), or anti-β_2GPI (IgG or IgM >99th percentile) *or* Single positive for LA	Venous thromboembolism	Long-term VKA: INR, 2.0-3.0
		Arterial thromboembolism	Long-term VKA: INR, 2.0-3.0 plus aspirin 100 mg/day
		Pregnant women with history of pregnancy complications	UFH plus low-dose aspirin
		Asymptomatic	No treatment; consider prophylaxis treatment in situations with increased risk (e.g., surgery, prolonged immobilization)
Low risk (OR, 1-5)	Single positive for aCL (IgG or IgM >40 GPL or MPL) or anti-β_2GPI (IgG or IgM >99th percentile)†	VTE	Long-term VKA: INR, 2.0-3.0
		Arterial thromboembolism	Long-term VKA: INR, 2.0-3.0
		Pregnant women with history of pregnancy complications	Early miscarriage (does not meet clinical criteria for obstetric APS); consider low-dose aspirin Late miscarriage: UFH plus low-dose aspirin
		Asymptomatic	No treatment but consider prophylaxis treatment in situations with increased risk (e.g., surgery, prolonged immobilization)

*Laboratory tests should be deferred until at least 12 weeks after the clinical event to avoid interferences of the acute phase of the disease. Earlier testing may yield false-positive results.

†More information from clinical studies on homogeneous cohort of patients with single positivity is needed.

whom were also positive for IgG aCL. However, anti-β2GPI IgA antibodies were reported to be significantly associated with thrombosis. A recent retrospective case-control study of 56 patients with isolated anti-β_2GPI IgA found that patients with this marker had significantly more thromboembolic events and higher polyclonal IgA levels than control participants. Anti-β_2GPI IgA was also found to be associated with an increased risk of thromboembolic events in patients with SLE.

Antiphospholipid antibodies of IgA isotype (either aCL or anti-β_2GPI) were not included in the international consensus statement on the criteria for APS classification. However, testing for the IgA isotype (particularly IgA anti-β_2GPI) was recommended in cases in which APS is suspected but the IgG and IgM test results are negative.

Annexin A5 Resistance Assay

The "annexin A5 resistance" (A5R) assay was designed to test for a specific pathogenic mechanism—the aPL antibody–mediated disruption of annexin A5 crystallization on phospholipid surfaces. As discussed earlier (see Pathophysiologic Mechanisms), annexin A5 forms a crystal shield on endothelial surfaces that is disrupted by anti-β_2GPI–β_2GPI complexes, thereby exposing more anionic phospholipids and accelerating coagulation reactions. The failure of annexin A5 to sufficiently prolong coagulation times because of interference by aPL antibodies is referred to as A5R. A study of 96 patients demonstrated significantly lower A5R values in APS patients with a history of thrombosis than in aPL antibody-positive patients with no thrombosis history, aPL antibody–negative patients with a thrombosis history, and healthy control participants. A recent study of 166 patients demonstrated a significantly lower A5R ratio in obstetric primary APS patients and thrombotic primary APS patients than in healthy control participants (Fig. 143-5).

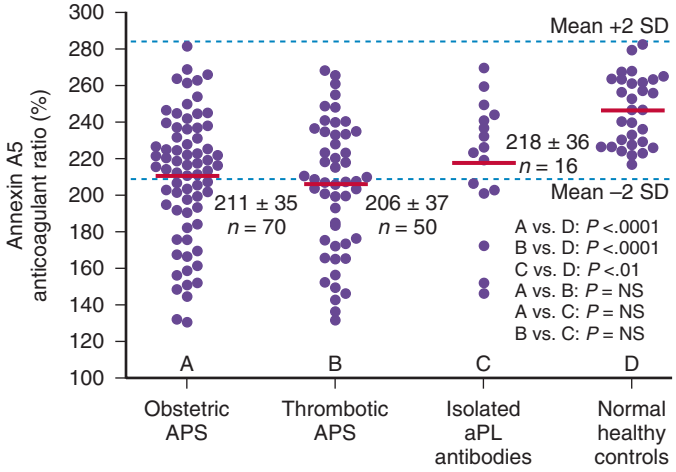

Figure 143-5 REDUCTION OF ANNEXIN A5 (AnxA5) ANTICOAGULANT RATIO ("ANNEXIN A5 RESISTANCE") IN PLASMAS FROM PATIENTS WITH ANTIPHOSPHOLIPID (aPL) SYNDROME (APS). The mean AnxA5 anticoagulant ratio for obstetric primary APS patients (group A) and thrombotic primary APS patients (group B) was significantly decreased compared with normal healthy control participants (both P <.0001). The patients with isolated aPL antibodies (group C) also showed significant reduction of AnxA5 anticoagulant ratios compared with the normal control participants (P = .007). There were no significant differences in AnxA5 anticoagulant ratio between groups A and B, between groups A and C, and between groups B and C. The *horizontal lines* show the mean of each group; the *dashed lines* show the mean ±2 standard deviation (SD) of the 30 normal healthy control participants. *(From Hunt BJ, Wu XX, de LB, et al: Resistance to annexin A5 anticoagulant activity in women with histories for obstetric antiphospholipid syndrome.* Am J Obstet Gynecol *205:485, 2011.)*

Anti–Domain I of β_2GPI Assay

This immunoassay identifies IgG antibodies against a specific amino acid sequence, G40-R30, within domain I of β_2GPI. A recent analysis of 198 samples from patients with a variety of autoimmune conditions revealed that in the 52 patients with anti-β_2GPI IgG antibodies, the antibodies could be divided into two groups: those that recognize domain I alone and those that react with all domains, the former having positivity for LA and an increased OR for thrombosis. A recent multicenter study of 442 patients who tested positive for anti-β2GPI antibodies reported that the detection of specific anti–domain I IgG antibodies was more strongly associated with thrombosis and obstetric complications than anti-β_2GPI antibodies detected using the standard anti-β_2GPI antibody assays. Anti–domain I IgG antibodies were present in plasma of 55% of patients, of whom 83% had a history of thrombosis (OR, .5) and 57% had pregnancy complications (OR, 2.4).

Antiprothrombin Antibody Assay

Prothrombin is considered the second major cofactor for aPL antibodies after β_2GPI. However, the evidence regarding the potential association of antiprothrombin antibodies and thrombosis is mixed. In a systematic literature review, a minority of studies (17 of 46) showed statistically significant associations. Overall, antiprothrombin antibody assays have not been considered to have sufficient clinical utility to be included in standard screening panels for aPL antibodies.

In a possible improvement over the standard antiprothrombin assay, it was recently reported that antibodies against the phosphatidylserine–prothrombin complex (aPS/PT) were closely associated with APS and LA. The presence of aPS/PT antibodies strongly correlated with the presence of LA, had a higher sensitivity and specificity than antiprothrombin antibodies alone for the diagnosis of APS and had comparable sensitivity and specificity to aCL for the diagnosis of APS. In addition, IgG aPS/PT antibodies were highly prevalent in APS patients compared with patients with other diseases with an OR of 12.8. Additional studies are needed to confirm these findings.

Antiphosphatidylserine Antibody Assay

Cardiolipin is normally present in mitochondrial membranes and is unlikely to be exposed to plasma coagulation proteins in vivo. Consequently, it was hypothesized that antibodies against phosphatidylserine may be more relevant pathophysiologically because this phospholipid is expressed on apoptotic cells, activated platelets, and syncytial cells. The utility of antiphosphatidylserine antibody determination is unclear. Although these studies have shown a relationship between antiphosphatidylserine antibodies and pregnancy complications, mainly recurrent miscarriages and reproductive failure, others have not. However, in patients with arterial thrombosis, antiphosphatidylserine antibodies have shown better correlation with APS than aCL antibodies.

Assays for Antibodies Against Other Phospholipids

Antibodies against the zwitterionic phospholipid phosphatidylethanolamine have been associated with thrombosis and with APC resistance. Some studies have suggested that antiphosphatidyethanolamine antibodies can occur in APS in the absence of antibodies against aCL or other anionic phospholipids. Antibodies against phosphatidylinositol antibodies were reported in young patients with cerebral ischemia. In a recent study of nearly 3000 women, IgG antibodies against phosphatidylinositol, phosphatidic acid, phosphatidylserine, and IgM antibodies against phosphatidylcholine were reported to be significantly elevated in patients with recurrent pregnancy loss, implantation failure, and unexplained fertility compared with fertile control

participants. Although some investigators have advocated testing for such antibodies, the most recent consensus statement concluded that testing patients for antibodies other than those directed against cardiolipin and β_2GPI was not worthwhile.

CLINICAL MANIFESTATIONS OF ANTIPHOSPHOLIPID SYNDROME

The clinical manifestations of APS can be categorized into "criteria manifestations" and "noncriteria manifestations." The "criteria manifestations" include vascular thrombotic events, obstetric APS, and CAPS. The "noncriteria manifestations" include other pathologic conditions that have been associated with aPL antibodies or with APS.

Criteria Manifestations of Antiphospholipid Syndrome

Systemic Vascular Thrombosis

Thrombosis in APS may occur spontaneously or in the presence of provoking factors such as estrogen replacement therapy, oral contraceptives, pregnancy, the postpartum state, vascular stasis, surgery, or trauma. Some patients with venous thrombosis—but generally not with arterial thrombosis—have concurrent genetic thrombophilic conditions such as heterozygosity for the factor V Leiden mutation. Patients may present with venous or arterial thromboembolism, but about 50% present with DVT of the lower extremities; other sites of venous thrombosis include the superior vena cava, axillary or subclavian veins, jugular vein, or abdominal or pelvic veins. In one study of patients with aPL antibodies and radiologic evidence of thrombosis, 59% had thrombosis limited to the venous circulation, 28% only had arterial thrombosis, and 13% had both.

The most significant risk factor for thromboembolic events in APS is a history of thromboembolism. The risk of recurrence in such patients is about 30% at 4 years and is particularly high in those who have both aCL and LA. The presence of anti-β_2GPI domain I antibodies also increases the risk of recurrence.

Reproductive Manifestations

Routine aPL antibody screening of asymptomatic obstetric patients is not warranted because of the high frequency of false-positive test results with the current tests and the absence of any specified treatment for asymptomatic patients who test positive. Most studies have estimated the prevalence of aPL antibodies among general obstetric populations to be less than 5%, and most of these aPL antibody-positive patients are not clinically affected. Reports from cohorts of obstetric patients with recurrent fetal losses indicate that approximately 16% to 38% had elevated aPL antibodies. Compared with aPL antibody–negative pregnant women, those with elevated aPL antibodies had significantly more obstetric complications, including preeclampsia, placental abruption, miscarriage, prematurity, intrauterine fetal death, intrauterine growth restriction, and oligohydramnios.

Women with obstetric APS generally present with a history of recurrent (i.e., three or more) miscarriages. In approximately half of patients, the pregnancy losses occur in the first trimester; other patients present with later losses, most in the second trimester, but some even later, including stillbirth. The specific pregnancy complications that define obstetric APS include the absence of an alternative explanation for the complications; three or more recurrent spontaneous first trimester miscarriages; or one midtrimester loss or stillbirth, episode of preeclampsia, preterm labor, placental abruption, intrauterine growth restriction, or oligohydramnios. Pregnant women with APS are also more likely to develop DVT during pregnancy or the puerperium. Rarely, pregnant patients develop CAPS.

A prior history of adverse clinical events—specifically, a history of previous pregnancy loss, complications, or thrombosis—is a better predictor for future pregnancy loss than the degree of laboratory abnormality. As mentioned previously, recent studies have shown that positivity for more than one assay—so called "multipositivity"—correlates with increased pregnancy-related morbidities. For example, one study showed that multipositivity but not single positivity for aPL antibodies was associated with antenatal and postnatal DVT. Another retrospective study of 128 pregnant women with APS found that patients with triple aPL positivity or previous thromboembolism appeared to have a higher likelihood of poor neonatal outcome than those with double or single positivity and no thrombosis history.

The current consensus is that aPL antibodies *do not* contribute to early reproductive failure (i.e., infertility). The Practice Committee of the American Society for Reproductive Medicine stated that "the assessment of aPL antibodies is not indicated among couples undergoing IVF [in vitro fertilization], and therapy is not justified on the basis of existing data." However, although an older study showed no relationship between the presence of aPL antibodies and implantation or ongoing pregnancy rates, a recent study reported that 8% to 9% of women with a history of unexplained infertility and recurrent implantation failure had more than one positive aPL antibody compared with only 1.5% of fertile negative control women and 11% of positive control women experiencing recurrent pregnancy loss. Studies suggest a possible nonthrombogenic mechanism of impaired trophoblastic differentiation, proliferation, and migration that may lead to the recurrent implantation failure seen in infertile women.

Neurologic Manifestations

Strokes are common in APS. In a large European cohort, stroke or transient ischemic attack (TIA) was the initial presentation in 29.9% of adults with APS, and recurrent stroke contributed to a significant proportion of deaths. In a study of Latin American adults with APS, 18% presented with stroke or TIA. A multinational lupus cohort showed that aPL antibody–associated stroke accounted for 11.8% of deaths. In the European CAPS registry, cerebral manifestations occurred in 62% of patients and were responsible for 13% of deaths.

Prospective analysis for the presence of aPL antibodies in stroke patients in the APASS demonstrated that elevated levels of aCL are associated with an increased risk of stroke but not other thromboembolic events. Patients who tested positive for *both* aCL and LA appeared to have more subsequent thrombo-occlusive events (with a trend that approached, but did not reach, statistical significance) than patients who tested negative for both (31.7% vs. 24.0%; $P = .07$). A subsequent study from the same group reported that elevated antibodies against β_2GPI and LA—and not aCL or antiphosphatidylserine—were the most significant risk factors for stroke. It is important to recognize that the presence of conventional risk factors for vascular disease adds to the baseline risk associated with the antibodies. In the RATIO study, women with LA positivity and other modifiable risk factors such as smoking or use of oral contraceptives had a higher risk of ischemic stroke. Patients with lupus and those with APS should undergo echocardiography because a high proportion have cardiac valve abnormalities (see later discussion).

The diagnosis of APS should be suspected in young patients with stroke or TIA, particularly those without other risk factors. Rates of stroke were higher in younger patients with APS, with a rate of up to 32% in a multinational childhood registry versus 16% to 21% in adult APS patients. Case-control and prospective studies have shown strong associations between aPL antibody positivity or LA positivity and ischemic strokes in young adults with an OR of 43.1 for positive LA test results. Younger patients presenting with stroke tended to have venous, rather than arterial, thrombosis with 7% of children presenting with cerebral vein thrombosis in the multinational childhood registry. In addition to their immediate impact, recurrent strokes may lead to multi-infarct dementia.

Cardiovascular Manifestations

Antiphospholipid syndrome should be considered in patients who present with coronary artery thrombosis in the absence of evidence of atherosclerosis and without typical risk factors. In the RATIO study, the presence of an LA was a significant risk factor for arterial thrombosis; the OR for MI was 5.3 and increased to 21.6 in women who used oral contraceptives and to 33.7 in those who smoked. Elevated anti-β_2GPI correlated with a small increase in the risk of stroke, but not MI. Antiprothrombin antibodies were reported to be a predictor of MI in middle-aged men, and one study found that these antibodies together with conventional cardiovascular risk factors increased the risk of MI in a multiplicative fashion.

Hepatic and Gastrointestinal Manifestations

The liver is the most commonly affected abdominal organ in APS, mainly via occlusion of hepatic vessels, including those supplying the biliary tree. The latter may present as acute acalculous cholecystitis with gallbladder necrosis. Gastrointestinal manifestations of APS also include esophageal necrosis with perforation, intestinal ischemia and infarction, pancreatitis, colonic ulceration, and giant gastric ulceration. APS has been reported in patients with mesenteric inflammatory venoocclusive disease and with mesenteric and portal vein thrombosis.

Renal Abnormalities

Patients with APS may present with vasoocclusive manifestations in the kidneys, including renal artery stenosis or thrombosis, renal infarction, renal vein thrombosis, and nonthrombotic manifestations (described in the section below). An entity known as *APS nephropathy* consists of vasoocclusive disease involving small intrarenal vessels; the features include fibrous intimal hyperplasia, focal cortical atrophy, and thrombotic microangiopathy. The acute form of this vascular nephropathy resembles other thrombotic microangiopathies, such as hemolytic uremic syndrome or thrombotic thrombocytopenic purpura (see Chapter 136). A chronic form is often clinically silent and consists of a vasoocclusive process that involves the entire renal vasculature, including the main renal artery and its branches, arterioles, glomerular capillaries, and renal veins.

Retinal Abnormalities

The diagnosis of APS retinopathy should be suspected in patients with diffuse retinal vasoocclusion, particularly when they have involvement of arteries and veins, neovascularization, and symptoms suggestive of a systemic rheumatologic disease. Elevated aPL antibody levels were present in 5% to 33% of patients with retinal vein occlusion. Cilioretinal artery occlusion, optic neuropathy, and severe vasoocclusive retinopathy have also been described with APS.

Other Organ Manifestations

Skin manifestations may be the first sign of APS in up to 3.5% of cases. Patients present with skin ulceration associated with skin necrosis.

Antiphospholipid antibodies have been described in patients with pulmonary hypertension. A multi-institutional study of 687 patients with chronic thromboembolic pulmonary hypertension reported that aPL antibodies were a significant risk factor. In one prospective trial of 38 consecutive patients with precapillary pulmonary hypertension, 30% had aPL antibodies with various phospholipid specificities.

Acute adrenal failure secondary to bilateral adrenal infarction or hemorrhage has been reported as the first manifestation of primary APS. aPL antibodies have also been associated with osteonecrosis.

Catastrophic Antiphospholipid Syndrome

Rare patients present with a *catastrophic* form of APS, which is characterized by severe widespread vascular occlusions and high mortality. The formal diagnostic criteria include involvement of at least three organs, systems, or tissues; development of manifestations simultaneously or within 1 week, histopathologic confirmation of small vessel occlusion; and laboratory confirmation of the presence of aPL antibodies (see Table 143-2). In contrast to the diagnostic criteria for APS, which exclude the diagnosis when histopathology reveals evidence of vasculitis, the diagnostic criteria for CAPS permit histologic evidence of vasculitis in association with thrombosis.

Of the 280 patients with CAPS reported in "The Registry of the European Forum on Antiphospholipid Antibodies for Patients With CAPS" (http://www.med.ub.es/mimmun/forum/caps.htm), 72% were female, with a mean age of 37 years (range, 11-60), 46% had primary APS, and 40% had SLE. In 46%, CAPS was their first manifestation of APS. The most common presentations were pulmonary (24%), neurologic (18%), and renal (18%) complications. Thrombosis affecting the renal, adrenal, splenic, intestinal, or pancreatic vessels was most commonly encountered. CAPS patients present with extensive VTE, respiratory failure, stroke, abnormal liver enzymes, renal impairment, adrenal insufficiency, and areas of cutaneous infarction. The respiratory failure is usually the result of acute respiratory distress syndrome and diffuse alveolar hemorrhage. Laboratory evidence of disseminated intravascular coagulation is frequently present (see Chapter 141). Table 143-5 describes the reported clinical manifestations from the CAPS registry. In marked contrast

Table 143-5 Clinical Manifestations Reported From the Catastrophic Antiphospholipid Syndrome Registry

Systemic vascular thrombosis	Extensive thrombosis affecting the renal, adrenal, splenic, intestinal, or pancreatic vessels was most commonly encountered with resultant multiorgan ischemia or infarction
Pulmonary manifestations	ARDS, diffuse alveolar damage, pulmonary embolism, dyspnea, hemoptysis
Neurologic manifestation	Stroke, TIA, seizures, encephalopathy, coma, psychosis, headache, vertigo, mononeuritis, peripheral neuropathy
Renal manifestations	Renal failure caused by thrombosis of renal arteries or veins, glomerulonephritis, interstitial nephritis, proteinuria, hematuria, hypertension
Dermatologic manifestations	Ulcerations attributable to microvascular infarction, livedo reticularis, skin ulcerations, skin necrosis, purpura rash, petechiae
Cardiovascular manifestations	Thrombotic occlusion of nonatherosclerotic coronary artery, thrombotic MI, valvular abnormalities, congestive heart failure, dilated cardiomyopathy, arrhythmia, pericardial effusion, atrial thrombosis
Hepatic and GI manifestations	Thrombotic occlusion of hepatic and mesenteric arteries and veins, Budd-Chiari syndrome, elevated liver enzymes, ascites, jaundice, cholestasis, cholecystitis, GI bleeding, diarrhea, vomiting, abdominal pain
Other manifestations	Acute adrenal failure caused by bilateral adrenal hemorrhagic infarction, avascular osteonecrosis, pancreatitis, blurred vision, decreased vision, diplopia

ARDS, Acute respiratory distress syndrome; *GI,* gastrointestinal; *MI,* myocardial infarction; *TIA,* transient ischemic attack.

to thrombotic thrombocytopenic purpura, another autoimmune thrombotic microangiopathy (see Chapter 136), in which recurrences are common, patients with CAPS who respond to treatment rarely experience a subsequent event.

Pediatric Antiphospholipid Syndrome

Antiphospholipid syndrome is increasingly recognized as a significant cause of thrombosis in the pediatric population. A European registry that included 121 cases described thrombotic manifestations similar to those seen in adults with APS. However, patients with primary APS tended to be younger and had a higher frequency of arterial thrombotic events. In contrast, those with secondary APS were older and had a higher frequency of venous thrombotic events associated with hematologic and skin manifestations. Children with rheumatic diseases who have persistently positive aPL are more likely to have resistance to annexin A5 anticoagulant activity than those with transiently positive antibodies. Although the catastrophic form of the syndrome has been reported in children, it is rare.

"Noncriteria" Clinical Manifestations Associated With Antiphospholipid Antibodies and Antiphospholipid Syndrome

"Noncriteria" Cardiovascular Manifestations

Cardiac Valve Abnormalities

About 35% of patients with primary APS have cardiac valve abnormalities that can be detected by echocardiography. When patients with cardiac valve disorders were evaluated for aPL antibodies, about 20% had aPL antibodies compared with 10% of matched control participants. Valvular abnormalities were reported in about 50% of patients with the combination of SLE and aPL antibodies; these abnormalities include leaflet thickening, vegetations, regurgitation, and stenosis. The mitral valve is most often affected followed by the aortic valve. In a prospective follow-up of 89 patients with severe, nonspecific valvular heart disease, thromboembolic events were significantly more frequent in the aPL antibody–positive group than in the aPL antibody–negative group; however, the presence of aPL antibodies was not an independent risk factor for thromboembolic events.

Coronary Artery Disease in the Absence of Thrombotic Occlusion

Antiphospholipid antibodies have been associated with increased susceptibility to coronary artery disease, particularly premature atherosclerosis. aPL antibodies appear to be a risk factor for adverse outcomes after percutaneous or surgical coronary revascularization procedures and for restenosis after coronary angioplasty. A carotid ultrasound study showed a correlation between aPL antibodies in young primary APS patients (age 37 years ± 11 years) and increased intimal thickness.

Peripheral Arterial Disease

Approximately one-third of patients with peripheral arterial disease undergoing bypass grafting procedures have elevated aPL antibody levels (mostly aCL antibodies). In one study, however, such patients did not have an increased risk for reocclusion compared with those who were aPL antibody negative, possibly because both groups received anticoagulant therapy.

"Noncriteria" Neurologic Manifestations

Other aPL antibody–associated neurologic abnormalities include migraines, seizures, chorea, Guillain-Barré syndrome, transient global amnesia, dementia, diabetic peripheral neuropathy, and orthostatic hypotension. In the pediatric APS registry, migraines (7%), chorea (4%), and epilepsy (3%) were the most common nonthrombotic neurologic manifestations.

In SLE patients, recurrent seizures are more common in those who have persistently elevated aCL antibodies. aPL antibody positivity has also been associated with cognitive impairment in lupus patients, especially in the areas of attention, psychomotor speed, and executive abilities. It has been proposed that aPL antibody–mediated damage to white matter tracts and basal ganglia structures may account for the multiple sclerosis–like features and movement disorders in APS patients.

Elevated aCL antibodies also occur in patients with multiple sclerosis, and these do not appear to be associated with an increased risk for thrombosis or stroke. In one series of patients with multiple sclerosis, 9% had IgG antibodies, and 44% had IgM antibodies, but there was no clinical distinction between aPL antibody–positive and –negative patients. Patients with psychotic disorders have also been reported to have an increased prevalence of LA and aCL antibodies that is not associated with antipsychotic medications. In this study, 32% (11 of 34) of the unmedicated psychotic patients had elevated aPL antibodies. These were not associated with an increased risk of thrombosis. Optic neuritis with elevated aPL antibodies has been described in the absence of retinal vasoocclusion. Sudden acute sensorineural hearing loss in patients with SLE or lupuslike syndromes has been described as a manifestation of APS.

"Noncriteria" Pulmonary Manifestations

Patients with APS may bleed into the acinar portions of the lung, which can lead to diffuse alveolar hemorrhage. Biopsy specimens reveal microvascular thrombosis, septal thickening caused by edema, neutrophilic septal infiltrates, and extravasation of red blood cells into the alveolar spaces. Because acute diffuse alveolar hemorrhage can occur in anticoagulated APS patients, it is thought that the lesions may be caused by vasculitis rather than thrombosis.

"Noncriteria" Gastrointestinal Manifestations

Antiphospholipid antibody levels are frequently elevated in patients with a variety of chronic liver diseases. In one prospective study of patients with liver disease, approximately half of the patients with alcoholic liver disease and one-third of those with chronic hepatitis C virus had elevated aPL antibody levels. The frequency was even higher in patients with severe cirrhosis. One review reported that about 20% of patients with chronic hepatitis B and hepatitis C had elevated aPL antibodies, most of which were cofactor independent (i.e., similar to the antibodies found in infections, which directly recognize phospholipid). Hepatitis C may be an exception because some patients present with "true" autoimmune aPL antibodies; the most common features reported were intraabdominal thrombosis and MI. Primary biliary cirrhosis has also been associated with aPL antibodies.

"Noncriteria" Renal Manifestations

Several nonthrombotic types of renal lesions have also been identified in APS patients. Patients with aPL antibodies may present with glomerulonephritis without vasoocclusive disease. A review of 29 consecutive renal biopsies from patients with primary APS performed at two institutions over 22 years described 20 cases of APS nephropathy and identified nine cases with distinct pathologic features, including membranous nephropathy, minimal change disease or focal segmental glomerulonephritis, mesangial C3 nephropathy, and pauci-immune crescentic glomerulonephritis.

Figure 143-6 LIVEDO RETICULARIS IN A WOMAN WITH ANTIPHOSPHOLIPID SYNDROME. *(From Ruiz-Irastorza G, Crowther M, Branch W, et al: Antiphospholipid syndrome.* Lancet *376:1498, 2010.)*

"Noncriteria" Dermatologic Manifestations

Livedo reticularis (Fig. 143-6) is relatively common, occurring in 24% of patients in a series that included 1000 patients with aPL. On rare occasions, patients present with a necrosing form. Livedo reticularis is usually widespread and can localize on nonadjacent areas on the limbs, trunk, and buttocks. Its prevalence is higher in APS associated with SLE compared with primary APS, in women compared with men, and in patients with high levels of aCL antibodies. Livedo reticularis may be associated with other manifestations of APS, such as cerebral or ocular ischemic arterial events (OR, 10.8; 95% CI, 5.2-22.5), seizures (OR, 6.5; 95% CI, 2.6-16), arterial events (OR, 6; 95% CI, 2.9-12.6), heart valve abnormalities (OR, 7.3; 95% CI, 3.6-14.7), and arterial systemic hypertension (>160-90 mm Hg; OR, 2.9; 95% CI, 1.5-5.7). Necrotizing vasculitis, livedoid vasculitis, superficial vein thrombosis, cutaneous ulceration and necrosis, erythematous macules, purpura, ecchymoses, painful skin nodules, and subungual splinter hemorrhages, anetoderma (macular atrophy), discoid lupus erythematosus, and cutaneous T-cell lymphoma have all been reported.

Other "Noncriteria" Hematologic Abnormalities

Thrombocytopenia

Thrombocytopenia occurs in a large proportion of APS patients, but the count is rarely low enough to cause bleeding complications or to preclude anticoagulant therapy. Most cases appear to be immune mediated (see Chapter 133). According to one study, the majority of patients with APS and thrombocytopenia were found to have antibodies against the platelet membrane glycoproteins, GPIIb/IIIa or GPIb/IX complexes (or both). However, in another study, no correlation was found between the presence of antibodies against platelet GPIIb/IIIa or GPIb/IX and thrombocytopenia, and the eluted platelet antibodies did not have any LA activity. Conversely, aPL antibodies and antibodies against platelet membrane GPs were present simultaneously in about 70% of patients with immune-mediated thrombocytopenia (ITP). In a prospective cohort study, the 5-year, thrombosis-free survivals of aPL antibody-positive and -negative ITP patients were 39% and 98%, respectively, indicating that thrombocytopenia itself is not protective against thrombosis in these patients.

Bleeding

The presence of a concurrent coagulopathy must be considered when patients with APS exhibit a bleeding tendency. Acquired hypoprothrombinemia can result in severe bleeding. This diagnosis may be missed if abnormal coagulation screening tests are attributed solely to the LA. To address this possibility, the level of prothrombin should be determined in patients with prolonged prothrombin times who are not receiving anticoagulant medications. Other causes of bleeding in the setting of APS include acquired thrombocytopathies (see Chapter 132), thrombocytopenia, acquired inhibitors against specific coagulation factors such as factor VIII (see Chapter 138), and acquired von Willebrand syndrome (see Chapter 140). It is important to note that the mechanism for AVWS in autoimmunity has not been established and that this deficiency of vWF is rarely associated with a demonstrable inhibitor.

TREATMENT OF PATIENTS WITH ANTIPHOSPHOLIPID SYNDROME

There is general agreement that patients with recurrent or spontaneous thrombosis require long-term anticoagulant therapy and that patients with recurrent spontaneous pregnancy losses require antithrombotic therapy for most of the gestational period and for the puerperium. There are differences of opinion regarding the approach to treatment of patients with single thrombotic events, a remote history of thrombosis, or a past history of provoked VTE. The recent categorization of patients into high-, medium-, and low-risk groups based on multipositivity of laboratory test results may help to guide management (see Table 143-4).

Thrombosis

The accumulated evidence from randomized controlled trials indicates that, in general, patients with APS and thrombosis should be treated with warfarin for the long term with doses adjusted to achieve a target international normalized ratio (INR) of 2.0 to 3.0.

Although there is a general consensus on this therapeutic range for venous thrombosis, there is controversy as to whether patients with arterial thrombosis warrant a higher intensity of anticoagulation because a retrospective study of a variety of patients with APS showed that an INR above 3.0 was necessary to prevent recurrences in this group of patients. Although two prospective, randomized, controlled trials reported no benefit and an increased risk of bleeding with higher intensity warfarin, neither study included a large number of APS patients with arterial thrombosis. Recent recommendations suggest that patients with MI and triple positivity should be treated with higher intensity warfarin (INR, 3.0-4.0) or usual intensity warfarin (INR, 2.0-3.0) plus low-dose aspirin. In addition, the triple-positive MI patients who undergo coronary stenting should receive triple therapy with warfarin (INR, 2.0-3.0), low-dose aspirin, and clopidogrel.

The LA may complicate monitoring of warfarin and heparin. The INR and aPTT can be artifactually elevated in some patients with APS and LA. A multicenter study reported that all but one of the commercial thromboplastins in use at nine centers provided acceptable INR values for APS patients with LA. If APS patients are given intravenous heparin, the baseline aPTT needs to be determined. If it is prolonged because of the LA, the heparin level can be monitored either by using an LA-insensitive aPTT reagent or with an anti–factor Xa assay. The need for monitoring can, in most patients, be obviated by the use of an LMWH.

Fibrinolytic therapy has been used in patients with primary APS with extensive DVT, acute ischemic stroke, or acute MI. The antimalarial drug hydroxychloroquine (HCQ) has been associated with a reduced risk of thrombosis in patients with APS and SLE. The potential effectiveness of this treatment is supported by findings in an animal model of aPL antibody thrombosis and by recent reports that HCQ directly disrupts aPL IgG–β_2GPI complexes and reverses the aPL antibody-mediated disruption of annexin A5 binding. At the time of writing, a prospective controlled, randomized trial is being planned by the APS ACTION! Network (http://www.apsaction.org)

to test whether this drug may be useful for treating asymptomatic individuals with positive aPL antibody assays who are considered to be at high risk for an initial thrombotic event.

The new oral thrombin and factor Xa inhibitors have not been evaluated in APS patients.

Stroke

There is controversy about the appropriate antithrombotic treatment of aPL antibody–associated stroke. Currently, most hematologists and rheumatologists view an APS-related stroke as no different than other arterial manifestations of APS, and they treat such patients with warfarin, although there is debate about the optimal intensity. Most stroke neurologists view APS-related strokes the same way they do strokes of other causes, and they accept the APASS study conclusion that treatment with aspirin is equivalent to warfarin but is associated with a lower risk of bleeding. Guidelines issued in 2006 from the American Heart Association and American Stroke Association stated that for patients with cryptogenic ischemic stroke or TIA associated with aPL antibodies, antiplatelet therapy is reasonable, and for patients who meet the criteria for APS with venous and arterial occlusive disease in multiple organs, miscarriages, and livedo reticularis, warfarin (target INR, 2.0-3.0) is reasonable.

Pregnancy Complications

A systematic review of treatments for women with a history of prior miscarriages and aPL antibodies concluded that combined unfractionated heparin (UFH) and aspirin reduces pregnancy loss by 54% compared with aspirin alone. Three trials of treatment with aspirin alone showed no significant reduction in pregnancy loss; intravenous immunoglobulin (IVIG), with or without UFH and aspirin, was associated with an increased risk of pregnancy loss or premature birth compared with UFH or LMWH combined with aspirin. Recently, a meta-analysis of five studies that included a total of 398 women concluded that adding UFH to low-dose aspirin significantly reduces first trimester losses but does not reduce late-pregnancy losses.

Despite the absence of "head-to-head" trials comparing LMWH with UFH, LMWH is often prescribed because it can be given once daily and the risk of heparin-induced thrombocytopenia and osteoporosis is lower than with heparin.

Women with a history of three or more spontaneous pregnancy losses and evidence of aPL antibodies should be treated with a combination of low-dose aspirin (75-81 mg/day) and prophylactic doses of UFH or LMWH. Treatment should be started as soon as pregnancy is documented and, when UFH is used, continued until delivery to reduce the rate of late complications. For patients treated with LMWH, clinicians frequently discontinue the drug in the last month of pregnancy and switch to treatment with UFH because of its advantages compared with LMWH (i.e., the shorter half-life and because the presence of significant concentrations in the bloodstream can be monitored with the simple aPTT assay) in case the patient goes into earlier labor. Low-dose UFH (i.e., 5000 U twice daily) or prophylactic dose LMWH should be started approximately 4 to 6 hours after delivery, provided that bleeding is not excessive, and continued until the patient is fully ambulatory. For patients with a history of VTE, anticoagulant therapy is warranted for at least 6 weeks after delivery. The optimal duration of postpartum treatment for patients without a history of thrombosis is unknown, but many physicians recommend prophylaxis for 6 weeks after delivery (see Chapter 142).

With the possible exception of women with SLE and high-titer triple-positive tests, the presence of elevated aPL antibodies in pregnant women without any history of spontaneous pregnancy losses, other attributable pregnancy complications, thrombosis, or embolism is not a sufficient indication for treatment. A prospective study of an untreated general obstetric population found that 2% to 3% of nonpregnant patients had low-titer increases of aCL antibodies, with a live birth rate of approximately 60% among these patients. It is therefore recommended that physicians should not include screening for aPL antibodies or LA in their routine prenatal screening panels.

Although prednisone was reported to improve the outcomes of pregnant patients with APS, any benefits were associated with significant toxicity. Corticosteroids or IVIG should be reserved for patients who are refractory to anticoagulant therapy, who have a severe immune thrombocytopenia or other significant bleeding problem, or who have a significant contraindication to heparin therapy. Treatment with prednisone and heparin increases risks of osteoporosis and vertebral fractures.

Catastrophic Antiphospholipid Syndrome

Patients with CAPS require aggressive treatment because of the high mortality. Conventional anticoagulant therapy is usually insufficient, and treatment modalities may include anticoagulation and immunosuppressive therapy with high-dose glucocorticoids, IVIG, cyclophosphamide, azathioprine, or rituximab. Plasmapheresis may be a helpful adjunct in some patients. According to the CAPS Registry, anticoagulation together with corticosteroids was most often used followed by the combination of anticoagulation, corticosteroids, and plasma exchange and/or IVIG. The highest recovery rate was obtained with the combination of anticoagulation, corticosteroids, and plasma exchange (77.8%) followed by anticoagulation, corticosteroids, plasma exchange, and/or IVIG (69%). The higher rate of the use of the last combination of treatment seems to be the main explanation for the reduction in mortality rate to 30% in CAPS.

Asymptomatic Antiphospholipid Antibody–Positive Patients

A recent, multicenter prospective study of 104 asymptomatic patients with triple positivity for aPL antibodies showed them to be at increased risk for a first thromboembolic event. Because aspirin alone did not effectively reduce this risk, it is recommended that anticoagulation be considered for some of these high-risk patients. After a careful risk-to-benefit analysis, anticoagulant therapy may be considered for some asymptomatic patients who are considered to be at very high risk, such as those with convincing family histories for thromboembolic complications of APS who themselves manifest significant laboratory abnormalities, patients with SLE who have significant multipositive aPL laboratory abnormalities, and patients who have other reasons for being at increased risk for thrombosis (e.g., severe valvular heart disease).

ASH evidence-based guidelines do not recommend prophylactic treatment with aspirin in asymptomatic aPL antibody–positive patients because the benefit is uncertain and there is a small risk of bleeding. However, some experts recommend low-dose aspirin prophylaxis in persistently aPL antibody–positive patients, in aPL antibody–positive patients with SLE, and in patients with obstetric APS. Heparin prophylaxis, which should be considered for all patients during periods of increased thrombotic risk (surgery or prolonged immobilization) are likely to be even more important for high-risk patients who also have aPL antibodies. The guidelines stress the importance of individual assessment of thrombotic risk in aPL antibody–positive patients. As with all patients, reversible thrombotic risk factors should also be addressed because these add to the risks of vascular occlusion in patients with positive aPL antibodies.

CHAPTER 144

VENOUS THROMBOEMBOLISM

Wendy Lim

Venous thromboembolism (VTE), encompassing both deep venous thrombosis (DVT) of the lower extremities and pulmonary embolism (PE), remains a common medical condition that is associated with significant morbidity and mortality.

Although VTE can occur in any vein, it most commonly occurs in the leg veins. Superficial venous thrombosis occurs most frequently in varicosities and usually is self-limiting and benign. In contrast, DVT is a more serious condition. Thrombi localized to the deep calf veins often are small and therefore less commonly associated with clinically important PE or postthrombotic syndrome, but proximal DVT involving the popliteal, femoral, or iliac venous system is complicated by PE in approximately 50% of cases.

The diagnosis of acute VTE is now being made more frequently because of increased diagnostic suspicion and the availability of reliable, noninvasive diagnostic tests. In hospitalized patients, this condition is largely preventable through the use of anticoagulant prophylaxis. In patients with established VTE, treatment is increasingly outpatient-based because of advances in anticoagulant therapy.

PATHOGENESIS OF VENOUS THROMBOEMBOLISM AND CLINICAL RISK FACTORS

Venous thrombi are composed predominantly of fibrin and red cells[1] and usually arise in the large venous sinuses in the calf, in valve cusp pockets in the deep veins of the calf or at sites of vessel damage. Pathologic or physiologic venous thrombosis occurs when activation of blood coagulation exceeds the ability of the natural anticoagulant mechanisms and the fibrinolytic system to prevent clot formation.[1] The current understanding of the pathogenesis of VTE was first described by Virchow more than 150 years ago.[2] He proposed that thrombotic disorders were associated with the triad of stasis, vascular injury, and hypercoagulability and that abnormalities in this triad result in thromboembolism. Stasis and vascular injury are the most frequent precipitants of VTE. In addition to activating coagulation, tissue damage can also impair fibrinolysis by reducing synthesis of tissue plasminogen activator (t-PA) and by increasing endothelial cell production of plasminogen activator inhibitor type 1 (PAI-1), the major inhibitor of the fibrinolytic pathway.[3]

Under normal circumstances, activated coagulation factors are diluted in the flowing blood and are neutralized by inhibitors on the surface of endothelial cells or by circulating antiproteinases.[4] Activated coagulation factors that escape regulation as a result of either reduced levels of inhibitors or because of generation of overwhelming amounts of these coagulation factors, trigger the coagulation system and fibrin formation. Homeostatic mechanisms, including activation of the fibrinolytic system with release of t-PA[5] and urokinase, are immediately invoked to reduce the likelihood of pathologic thrombus formation.

THROMBOGENIC FACTORS

Activation of Blood Coagulation

With the exception of small amounts of factor VII, the coagulation factors circulate as inactive protein precursors, or zymogens. Each zymogen is converted into an active enzyme that then activates the next zymogen in the coagulation pathway (see Chapter 124).[6] Traditionally, the coagulation system has been divided into the intrinsic, extrinsic, and common pathways. Although these pathways reflect the way coagulation is measured in the laboratory, they do not reflect how coagulation occurs in vivo. In vivo, coagulation is primarily initiated via the tissue factor pathway. In this pathway, a proportion of the circulating activated factor VII—factor VIIa—binds to tissue factor at sites of vascular injury. The tissue factor–factor VIIa complex then activates both factor IX and factor X.[7] Levels of factor VIIa can be increased by factor Xa; however, this reaction is rapidly downregulated by tissue factor pathway inhibitor (TFPI). TFPI renders factor Xa inactive by complexing with it; the TFPI–factor Xa complex then binds the factor VIIa–tissue factor complex and prevents further activation of factor X.[8]

In the presence of activated factor V, phospholipid, and calcium, factor Xa completes the coagulation system by converting prothrombin to thrombin. Thrombin then converts fibrinogen to fibrin, activates platelets, and activates factor XIII, which, in the presence of calcium, cross-links fibrin and stabilizes the fibrin clot. To ensure continuous generation of thrombin, thrombin and, to a lesser extent, factor Xa activate factor VIII and factor V, markedly accelerating the coagulation reactions involving these two cofactors. Thrombin also activates factor XI, which in turn activates additional factor IX, establishing a positive feedback loop.[6]

Coagulation may be activated by contact of factor XII with collagen on exposed subendothelium of damaged vessels, by contact with prosthetic surfaces, or by polyphosphates released from activated platelets. The importance of this pathway in thrombosis is uncertain, but studies in mice deficient in factor XII or factor XI exhibit attenuated thrombus formation at sites of injury, suggesting that the contact pathway plays a part in thrombus stabilization. Under most situations, coagulation is initiated by the exposure of blood to tissue factor made available locally as a result of vascular wall damage,[7] by activation of endothelial cells, or by activated monocytes that migrate to areas of vascular injury.[9] Factor X can be activated directly by extracts of malignant cells that contain a cysteine protease,[10] which may be one of the mechanisms by which thrombosis is induced in patients with cancer. A factor elaborated by hypoxic endothelial cells also can directly activate factor X,[11] potentially leading to thrombosis in patients with severe venous stasis in whom stagnant hypoxia occurs in the valve cusps.

Venous Stasis

Venous stasis is produced by immobility, venous obstruction, increased venous pressure, venous dilation, and increased blood viscosity. Venous return from the lower extremities is enhanced by venous valves, which prevent blood from pooling in the lower legs, and by contraction of the calf muscles, which propels blood upward from the extremities. Venous stasis may contribute to thrombogenesis by allowing stagnation of the blood with associated local hypoxia, which stimulates endothelial cell release of an activator of blood coagulation.[11]

Immobility

Venous thrombosis can occur in immobilized persons because blood pools in the intramuscular sinuses of the calf, which are dilated during recumbency. Many clinical examples highlight the role of stasis in the pathogenesis of VTE. For example, the prevalence of VTE found at autopsy is markedly increased in persons who were confined to bed for more than 1 week before death. Preoperative immobility is associated with a higher frequency of perioperative VTE, and postoperative immobility contributes to the high incidence of postoperative VTE in patients who have undergone hysterectomy, transabdominal prostatectomy, hip surgery, knee surgery, or surgery for fractures of the lower limb. The effect of immobility on thrombus formation is well illustrated by comparing the location of thrombosis in patients with paraplegia with that in patients who have had a stroke. Whereas thrombosis occurs with equal frequency in both legs in patients with paraplegia, it occurs more frequently in the paralyzed limb in patients who have had a stroke.

Venous Obstruction and Increased Venous Pressure

Venous obstruction contributes to the risk of VTE in patients with pelvic tumors and to recurrent venous thrombosis in patients with persistent obstruction because of proximal vein thrombosis. Raised central venous pressure produces venous stasis in the extremities, which may explain the high prevalence of venous thrombosis in patients with congestive heart failure. A similar mechanism may underlie the propensity for thrombosis in the left leg during pregnancy, presumably from obstruction of the left common iliac vein by the right common iliac artery, which is accentuated by the presence of the gravid uterus.[12]

Increased Blood Viscosity and Venous Dilation

Venous stasis can be caused by increased blood viscosity or venous dilation. The blood viscosity can be increased by polycythemia, hypergammaglobulinemia, dysproteinemias, or increased fibrinogen levels. Stasis because of venous dilation may contribute to the increased risk of thromboembolism in patients with varicose veins and in elderly patients, particularly if they are bedridden. The capacity of estrogens to cause venous dilation may contribute to the increased prevalence of thrombosis during pregnancy,[13] in patients taking estrogen-containing oral contraceptive pills,[13] and in women taking postmenopausal estrogen replacement therapy.[14-16]

Vessel Wall Damage

Damage or injury to the vascular endothelium exposes tissue factor, which triggers coagulation. Furthermore, the exposure of blood to the subendothelium leads to platelet adhesion, activation, and aggregation.

The vascular endothelium can be damaged by direct trauma, or it can be perturbed by exposure to endotoxin, inflammatory cytokines such as interleukin-1 and tumor necrosis factor, thrombin, or low oxygen tension. Perturbed endothelial cells synthesize tissue factor and PAI-1 and internalize thrombomodulin, promoting thrombogenesis.[17] Furthermore, damaged endothelial cells may produce less t-PA, the principal activator of intravascular fibrinolysis.

Direct venous damage may lead to venous thrombosis in patients undergoing hip surgery, knee surgery, or varicose vein stripping and in patients with severe burns or lower limb trauma.

PROTECTIVE MECHANISMS

Endothelial Protective Mechanisms

Normal vascular endothelium is nonthrombogenic to flowing blood. Endothelial cell surface glycosaminoglycans, thrombomodulin, and endothelial protein C receptor (EPCR) are potent inhibitors of coagulation, and vessel wall generation of prostacyclin, nitric oxide and synthesis of plasminogen activators limit platelet aggregation and fibrin deposition.

Heparan sulphate, thrombomodulin, and EPCR present on the luminal surface of endothelial cells are important modulators of thrombin activity. Heparan sulfate, a glycosaminoglycan similar to heparin, catalyzes the inhibition of thrombin and factor Xa by antithrombin.[4] Thrombomodulin serves as a surface-bound receptor for thrombin.[17] After being complexed with thrombomodulin, thrombin undergoes a conformational change that markedly alters its substrate specificity such that thrombin is no longer capable of activating platelets, of converting fibrinogen to fibrin, or of activating factors V, VIII, and XIII.[4] Rather, complexed thrombin acquires enhanced ability to activate protein C, which in turn proteolytically inactivates factors Va and VIIIa. This reaction requires protein S as a cofactor. Thus, when bound to thrombomodulin, thrombin not only loses its procoagulant activity but, by activating protein C, triggers a potent anticoagulant pathway. EPCR enhances protein C activation by binding protein C and presenting it to the thrombin–thrombomodulin complex for activation.

Generation of plasminogen activators[18] by vascular endothelium limits fibrin deposition, and platelet aggregation is inhibited by the release of prostacyclin (prostaglandin I2) and endothelium-derived nitric oxide.[19] Endothelial cell affinity for t-PA, plasminogen, and activated protein C and protein S also may contribute to the resistance of the vessel wall to thrombosis.[4] Plasminogen binds to the cell surface, where it can be activated to plasmin by t-PA, thereby promoting local fibrinolytic activity.

Inhibitors of Blood Coagulation

Activated coagulation factors are serine proteases, and their activity is modulated by several naturally occurring plasma inhibitors. The most important inhibitors of the blood coagulation system are antithrombin, protein C, and protein S.[4] An inherited deficiency of one of these three proteins was found in 11% of patients enrolled in a prospective study of 2132 consecutive patients presenting with VTE.[20] Abnormalities in the fibrinolytic system, including congenital dysfibrinogenemias and deficiency of plasminogen, can also predispose the affected person to thromboembolism.

HYPERCOAGULABLE STATES

Other potential causes of VTE are hypercoagulable states, including those associated with deficiencies of antithrombin and proteins C and S, the factor V Leiden and prothrombin G20210A mutations, hyperhomocysteinemia, and the presence of antiphospholipid antibodies. Hypercoagulable states are the subject of Chapter 142.

NATURAL HISTORY OF VENOUS THROMBOEMBOLISM

Most thrombi are asymptomatic and confined to the intramuscular veins of the calf. These calf vein thrombi often undergo spontaneous

lysis and rarely produce long-term sequelae.[21] In contrast, complete lysis of proximal vein thrombosis is uncommon even when heparin treatment is given.[22]

The symptoms and signs of VTE are caused by obstruction to venous outflow, inflammation of the vessel wall or perivascular tissues, or embolization of thrombus into the pulmonary circulation. Asymptomatic PE is detected by perfusion lung scanning in approximately 50% of patients with documented proximal vein thrombosis.[23] Most clinically significant and fatal pulmonary emboli probably arise from DVT in the proximal veins of the legs. Although PE also may complicate calf vein thrombosis, these emboli tend to be smaller in size, and PE occurs less commonly than in patients with proximal DVT.[23] Asymptomatic DVT is found in 70% of patients who present with confirmed PE.[24] These thrombi usually are large and involve the proximal veins.

Extensive DVT causes venous valvular damage, which leads to the postthrombotic syndrome.[25] Patients with a previous history of DVT are at increased risk of recurrence, particularly when patients are exposed to high-risk situations.[26]

PROGNOSIS OF VENOUS THROMBOEMBOLISM

Untreated or inadequately treated VTE is associated with a high complication rate, which can be decreased markedly by adequate anticoagulant therapy. Approximately 20% of untreated asymptomatic calf vein thrombi and 20% to 30% of untreated symptomatic calf vein thrombi extend into the popliteal vein. When extension occurs and is untreated, it is associated with a 40% to 50% risk of clinically detectable PE.[21] Patients with proximal vein thrombosis who receive inadequate treatment[27] have a 47% frequency of recurrent VTE over 3 months, and patients with symptomatic calf vein thrombosis who receive a 5-day course of intermittent intravenous unfractionated heparin (UFH) without continuing oral anticoagulants have a recurrence rate greater than 20% over the next 3 months.[28]

By contrast, clinically detectable recurrence occurs in fewer than 2% of patients with proximal vein thrombosis during the initial period of UFH therapy[23] if an adequate anticoagulant response is achieved, and the recurrence rate during the subsequent 3 months of treatment with oral anticoagulants or moderate doses of subcutaneous UFH is 2% to 4%.[27,29,30] After 3 months of anticoagulant therapy, the recurrence rate is 5% to 10% in the subsequent year.[27,29,30] Patients whose first episode of VTE was idiopathic and those who have ongoing risk factors, such as prolonged immobilization or cancer, have a higher risk of recurrence.

The significance of asymptomatic calf DVT discovered incidentally by screening venography after orthopedic surgery is unclear, but the risk of clinical sequelae from these thrombi is low.[31] As a result, if adequate perioperative thromboprophylaxis is given, it is probably unnecessary to perform screening tests for DVT in asymptomatic patients at the time of hospital discharge.

POSTTHROMBOTIC SYNDROME

The postthrombotic syndrome is caused by venous hypertension, usually resulting from valve damage. Valve damage results in malfunction of the muscular pump mechanism, which leads to increased pressure in the deep calf veins during ambulation. The high pressure ultimately renders the perforating veins of the calf incompetent, so that blood flow is directed from the deep veins into the superficial venous system during muscular contraction. This leads to edema and impaired viability of subcutaneous tissues and, in its most severe form, to venous ulceration. Outflow obstruction initially may be bypassed by the development of collateral veins, but with time, the veins distal to the obstruction become dilated, and their valves become incompetent.

In patients whose thrombosis extends into the iliofemoral veins, the leg swelling at initial presentation may not resolve entirely. This is in contrast to patients with less extensive proximal vein thrombosis, in whom the swelling may subside after initial treatment but recur months or years later. Other symptoms and signs of the postthrombotic syndrome may be delayed for 5 to 10 years after the initial thrombotic event. These symptoms include pain in the calf that is relieved with rest and leg elevation, skin pigmentation and induration around the ankle and lower third of the calf, and ulceration in the region of the medial malleolus.

Patients with extensive thrombosis involving the iliofemoral vein frequently have greater disability and may have venous claudication, characterized by incapacitating, bursting pain with exercise.[32] This complication rarely occurs in patients with thrombosis involving the more distal veins.

The frequency with which postthrombotic syndrome occurs after VTE is controversial. Prandoni and colleagues[33] demonstrated that 29% of patients with acute DVT will develop the syndrome after 8 years of follow-up; however, other investigators have found a much lower rate.[34] The development of ipsilateral recurrent thrombosis was associated with a large increase in risk for the development of postthrombotic syndrome.

Treatment for acute DVT may reduce the long-term risk of postthrombotic syndrome. In addition, the use of below-knee graduated compression stockings has been shown to reduce the risk of postthrombotic syndrome in patients with DVT.[35]

DIAGNOSIS OF VENOUS THROMBOEMBOLISM

The diagnosis of VTE is based on objective testing, as opposed to clinical assessment, which may be subjective.

DEEP VENOUS THROMBOSIS

Clinical Manifestations

Deep venous thrombosis classically causes swelling, pain and erythema of the affected extremity. Proximal DVT is more likely to be symptomatic than calf vein thrombosis. Patients with massive thrombosis involving the iliac and femoral veins may present with phlegmasia cerulea dolens, which is severe leg pain with swelling, cyanosis, venous gangrene, compartment syndrome, and arterial compromise. Patients with phlegmasia cerulea dolens may experience circulatory collapse and shock, which may result in death or loss of the affected limb.

Differential Diagnosis

The differential diagnosis of patients with suspected DVT includes musculoskeletal disorders (muscle or tendon strains or tears), lymphatic obstruction, venous insufficiency, a ruptured popliteal (Baker) cyst, cellulitis, sciatica, muscle hematoma, and the postthrombotic syndrome.

OBJECTIVE DIAGNOSTIC TESTS FOR DEEP VENOUS THROMBOSIS

Both invasive and noninvasive tests are useful for the diagnosis of DVT. Venography is the only invasive test of proven value, and venous compression ultrasonography is the most widely studied and used noninvasive test. Although other imaging modalities have been studied (e.g., magnetic resonance direct thrombus imaging), these are not commonly performed.

Venography

Venography remains the reference standard for the diagnosis of DVT, although it is performed increasingly less frequently.[36] It is technically difficult, and its proper execution and interpretation

require considerable experience. Venography may produce superficial phlebitis and can cause DVT,[36] but with good technique, ascending venography outlines the entire deep venous system of the lower extremities, including the calf and iliac veins. It is currently used only when noninvasive testing is not feasible or the results of such testing are inconclusive.

Venous Compression Ultrasonography

Venous ultrasonography is performed using a high-resolution real-time scanner equipped with a 5-MHz electronically focused linear array transducer. The common femoral vein and femoral artery are first located in the groin, with the patient in a supine position. The superficial femoral vein is then examined along its course. Next, the popliteal vein is located and examined down to the level of its trifurcation into the peroneal and tibial veins. At each of these locations, the vein being examined is compressed gently but firmly with the transducer probe, and the results are observed on the monitor. Hard copies from freeze-frame images of both stages of the procedure are obtained and serve as a permanent record.

In symptomatic patients, venous compression ultrasonography has a sensitivity and specificity for detection of proximal DVT (femoral or popliteal vein) of more than 95%.[37] However, ultrasonography is less sensitive for detection of calf vein thrombosis.[38] Ultrasound examination can be repeated 7 days after the initial study to increase its sensitivity for detection of clinically important calf vein thrombosis and to improve the safety of diagnostic strategies that do not include venography in patients with suspected calf vein thrombosis. This strategy will detect the 10% to 30% of calf vein thrombi that extend proximally. If the ultrasound examination result remains negative after 7 days, the risk of clinically important proximal extension is negligible, and it is safe to withhold antithrombotic treatment.[39-42]

If the field of examination is extended to the distal popliteal vein and the proximal deep calf veins, venous ultrasonography detects approximately 50% of calf vein thrombi in symptomatic patients.[44,45] Although there are reports that ultrasound examination of the calf can reliably detect thrombi, most such reports have not used venography as their reference standard. Furthermore, whether the value of this test is maintained when it moves from highly specialized vascular laboratories into community ultrasonography laboratories is unknown. A potential limitation of venous ultrasonography is its inability to visualize the iliac veins and the segment of the superficial femoral vein within the femoral canal. This is not a serious limitation because isolated thrombi within the femoral canal or the iliac vein are rare.[46] Furthermore, the obstruction produced by iliac vein thrombi often limits the compressibility of the common femoral vein segment and hence will be detected indirectly. Doppler color flow can also be used to assess for blood flow and occlusion within a vein. The combination of compression ultrasonography and Doppler is often referred to as duplex ultrasonography.

D-Dimer Assays

D-dimer assays use mono- or polyspecific antibodies against D-dimer to provide quantitative or qualitative data on the concentration of D-dimer in whole blood or plasma. D-dimer is the product of lysis of cross-linked fibrin and the levels of D-dimer are increased in patients with acute VTE. However, the test is nonspecific because the level of D-dimer is increased in a variety of other conditions, including malignancy, inflammatory conditions, and infections. Therefore, the D-dimer assay is most useful as a tool to rule out suspected DVT.[47,48]

D-dimer assays have two principal limitations: (1) A positive test result is nonspecific and should not be used as the sole criterion for diagnosis of VTE, and (2) numerous test kits are available that have different sensitivities for VTE. Thus D-dimer results are not interchangeable between kits. (Assays also use different standards; some use fibrinogen, others use D-dimer. This leads to confusion in reporting because the cut-offs are different depending on which standard is used.) This has led to confusion among clinicians regarding the use of D-dimer assays, and this confusion is exacerbated by the fact that the use of an insensitive D-dimer assay to rule out VTE could result in omission of required diagnostic testing, placing patients at risk for PE and death.

The optimal setting for use of a D-dimer assay is in the assessment of patients with a low clinical pretest probability of VTE. The combination of a low pretest probability (determined using a validated scoring system) and a negative result with a validated D-dimer assay rules out the diagnosis of acute DVT, obviating the need for additional testing. Some D-dimer kits have been studied in patients with low and moderate pretest probabilities of DVT and have been shown to reliably exclude DVT in both patient groups.[49,50] Evaluation of the levels of D-dimer may be of particular value in patients with suspected recurrent VTE, and it may assist in decision making about optimal duration of anticoagulation.[51]

DIAGNOSTIC STRATEGIES FOR DEEP VENOUS THROMBOSIS

Diagnostic algorithms for the noninvasive diagnosis of clinically suspected VTE are presented in Fig. 144-1. If compression ultrasonography is not immediately available, patients can be empirically

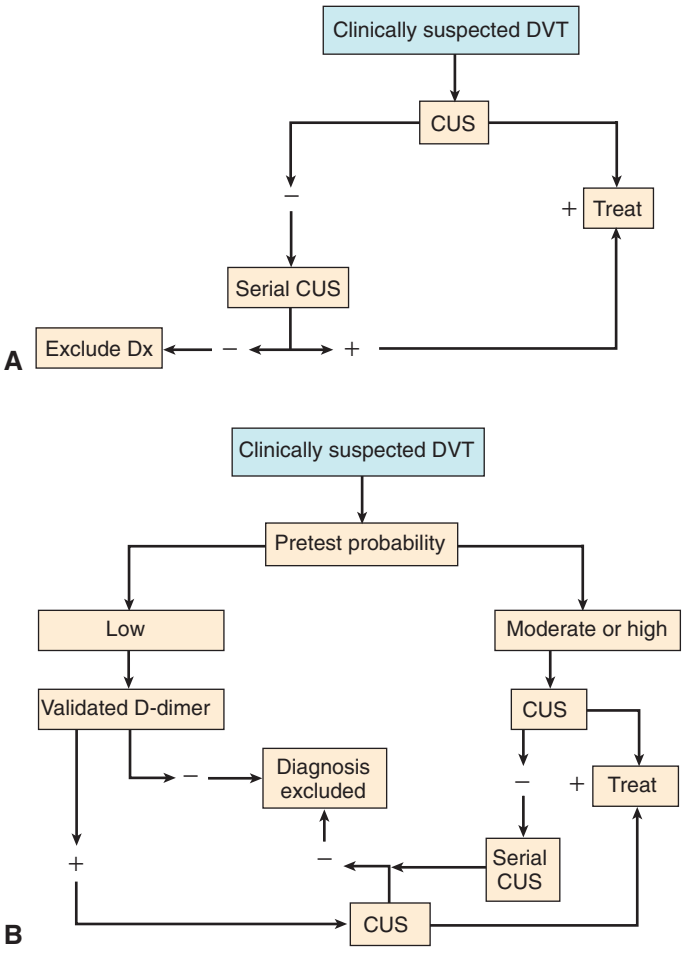

Figure 144-1 DIAGNOSTIC ALGORITHMS FOR THE MANAGEMENT OF PATIENTS WITH SUSPECTED DEEP VENOUS THROMBOSIS (DVT). **A**, Ultrasound examination–based strategy. **B**, Clinical probability–based strategy. *CUS,* Compression ultrasound.

anticoagulated with a therapeutic dose of low-molecular-weight heparin (LMWH) and can then return for diagnostic testing on the subsequent day. In assessing patients with suspected DVT, patients can be classified into high-, intermediate-, or low-probability groups based on their clinical manifestations and the presence or absence of risk factors such as recent immobilization, hospitalization within the past 6 months, or malignancy.[43] In one series, patients with the classic symptoms and signs of DVT and who had at least one risk factor had an 85% probability of DVT, but those with atypical symptoms and no risk factors had only a 5% probability of DVT. These low- and high-pretest probabilities can be combined with the results of objective noninvasive tests to make clinical decisions. A low clinical pretest probability and a negative result on noninvasive testing can be used to exclude a diagnosis of DVT and obviate further testing, but a high clinical pretest probability and a negative noninvasive test result should prompt further investigation with either venography or serial ultrasonography.

In approximately 70% of patients referred for clinically suspected DVT, the diagnosis will be excluded by objective tests.[39,40] Of the 30% who have DVT, approximately 85% will have proximal vein thrombosis, and the remainder will have thrombosis confined to the calf.[39,40]

PULMONARY EMBOLISM

Clinical Manifestations

The most frequently reported symptom of PE is dyspnea.[52,53] Chest pain is common and typically pleuritic in nature but may be substernal and compressing. Hemoptysis is a less frequent feature.[24,52,53]

The physical signs of PE are nonspecific. Syncope usually is associated with massive PE and is caused by a reduction in cardiac output. This in turn results in hypotension and transient impairment of cerebral blood flow.

Although 70% of patients with PE have venographic evidence of thrombosis at presentation, fewer than 20% of these patients have leg symptoms.[24] Massive PE causes tachypnea, tachycardia, cyanosis, and hypotension. In these patients, cardiac examination may reveal a right ventricular heave, a loud pulmonary second sound, and a gallop rhythm. Physical examination of the chest may be normal, or nonspecific abnormalities may be detected. Patients with pulmonary infarction or atelectasis may have reduced movement of the affected portion of the chest.

Differential Diagnosis

The differential diagnosis of dyspnea and pleuritic chest pain, in addition to PE, includes pneumonia, pleurisy, chest wall pain, pericarditis, atelectasis, pneumothorax, acute bronchitis, acute bronchiolitis, and acute bronchial obstruction as a result of mucous plugging or bronchoconstriction.

Diagnosis

The clinical diagnosis of PE requires objective testing. The chest radiograph is not specific for PE and usually does not show any diagnostic abnormality. Nevertheless, it is useful in excluding other causes for the presenting symptoms (e.g., pneumothorax) and is essential for interpreting ventilation/perfusion (V/Q) lung scan findings. The electrocardiogram (ECG) findings are frequently normal or show nonspecific abnormalities. However, in the appropriate clinical setting, ECG evidence of right ventricular strain is strongly suggestive of PE. Elevated levels of cardiac troponin can result from right ventricular strain and associated myocardial ischemia.[54]

OBJECTIVE DIAGNOSTIC TESTS FOR PULMONARY EMBOLISM

Pulmonary Angiography

Pulmonary angiography is the reference standard for establishing the presence or absence of PE. However, similar to venography of the lower extremities, it requires technical expertise and is done only when noninvasive testing is not feasible or the results of such testing are nondiagnostic. Selective angiography and magnification views improve resolution and reduce the risk of the procedure. When pulmonary angiography is adequately performed, a negative result excludes the diagnosis of PE. Unless the tertiary pulmonary arteries are visualized in a patient with a small perfusion defect, however, the diagnosis of PE cannot be excluded.[55]

Arrhythmias, cardiac perforation, cardiac arrest, and hypersensitivity reactions to contrast material occur in 3% to 4% of patients undergoing pulmonary angiography.[56] Patients with a history of allergy to radiopaque dye should not undergo pulmonary angiography.

Helical Computed Tomography Scanning

Helical or spiral computed tomography (CT) scanning of the chest has emerged as the preferred test for the diagnosis of PE. When performed in experienced clinical centers with use of validated scanning protocols, helical CT scanning is a useful tool to rule out PE in patients with compatible clinical symptoms. For example, in one study in which patients with suspected PE were evaluated with single-detector helical CT scanning and those with negative or inconclusive findings on CT scanning underwent ultrasonography of the lower extremities on the day of presentation and on days 4 and 7 after scanning, 124 of 510 enrolled patients had PE.[58] In 130 patients, an alternate diagnosis for their chest symptoms was found with the CT scan, 10 patients either could not have a CT performed or had a uninterpretable scan, and 248 patients had normal scans. Two of these 248 patients had proximal DVT on their initial ultrasound study, and all other patients had normal findings on serial ultrasound examinations. This and other similar studies suggest that if used correctly, helical CT scanning is a useful test in patients with suspected PE. In fact, systematic reviews suggest that a correctly done spiral CT effectively rules out PE in patients suspected to be at low or moderate risk of this complication.[59]

Ventilation/Perfusion Lung Scan

The lung scan consists of a perfusion and a ventilation component. For the perfusion component, particles of isotopically labeled microaggregates of human albumin are injected intravenously and become trapped in the pulmonary capillary bed. Their distribution reflects lung blood flow and is recorded with an external photoscanner. A normal perfusion scan excludes PE, but an abnormal perfusion scan is nonspecific.[24,53,57]

Ventilation lung scanning is performed using either radioactive gases or aerosols that are inhaled and exhaled by the patient while a gamma camera records the distribution of radioactivity within the alveolar gas exchange units. The purpose of ventilation imaging is to improve the specificity of perfusion scanning for the diagnosis of PE. A high-probability V/Q scan (in which a segmental or greater area is ventilated but not perfused) has a positive predictive value for PE of more than 90%, obviating the need for angiography.

The relative ease and accessibility of CT scanning has reduced the use of V/Q scanning for the diagnosis of PE. However, V/Q scanning is frequently preferred in two patient populations: patients with impaired renal function and young women. In patients with impaired renal function, contrast dye administration for the CT scan can induce contrast nephropathy, increasing mortality up to 30% after such a procedure. Furthermore, CT scanning results in radiation

exposure, which is associated with a small increase in the risk of subsequent cancer. Although this risk varies depending on a number of factors, concern about increasing the risk of breast cancer in young women has prompted use of V/Q scanning preferentially in this population. V/Q lung scanning should ideally be reserved for patients with normal chest radiographs because preexisting lung disease may result in indeterminate scans.

Diagnostic Strategy for Pulmonary Embolism

Patients with large perfusion defects (involving one or more segments or more extensive defects) and a V/Q mismatch have a 90% probability of PE. Patients with a normal perfusion scan have less than a 2% probability of having PE, excluding the diagnosis. However, most patients who have V/Q scanning performed will have neither of these findings; rather, they will have either matched defects or small perfusion defects (indeterminate scan).[24,53,57] Patients with these findings require further investigation with either pulmonary angiography or objective tests for DVT of the lower extremities. A patient with suspected PE, an indeterminate V/Q scan result, and positive findings on compression ultrasound examination of the lower extremities can be assumed to have PE. A patient with suspected PE, an indeterminate scan, and a negative result on leg ultrasound examination requires additional testing because the thrombus may have completely embolized to the lungs.[24,53]

A diagnostic algorithm for the management of clinically suspected PE is shown in Fig. 144-2. After a history and physical examination, ECG, and chest radiography, all patients with suspected PE should undergo helical CT scanning or V/Q lung scanning. A negative helical CT or a normal perfusion lung scan result rules out clinically significant PE, and anticoagulant therapy can be withheld. If an intraluminal filling defect is seen on helical CT or the perfusion scan demonstrates one or more segmental (or larger) defects and ventilation to these regions is normal, a diagnosis of PE is made. Although a V/Q mismatch supports a diagnosis of PE, a V/Q "match" does not exclude PE, and further objective testing is required in these patients. Similarly, the diagnosis of PE cannot be excluded in patients with small perfusion defects (one or more subsegmental defects) or those with indeterminate lung scan findings (in which the perfusion defects correspond with abnormalities on the chest radiograph). In these patients, venous ultrasonography should be performed. If DVT is documented, a diagnosis of PE can be assumed, and anticoagulant therapy should be started. However, if results on these tests are negative, additional objective investigations (e.g., pulmonary angiography) are required in patients with a high clinical pretest probability. For those with a lower pretest probability of PE, an alternative strategy is to withhold anticoagulants and to perform serial noninvasive tests to detect venous thrombosis. In patients with a low or low to moderate pretest probability of PE, a D-dimer test may prove useful. If the D-dimer assay result is negative, further testing can be avoided, but if it is positive (increasing the likelihood of acute thrombosis), further testing (e.g., venous compression ultrasonography) is warranted.[60,61]

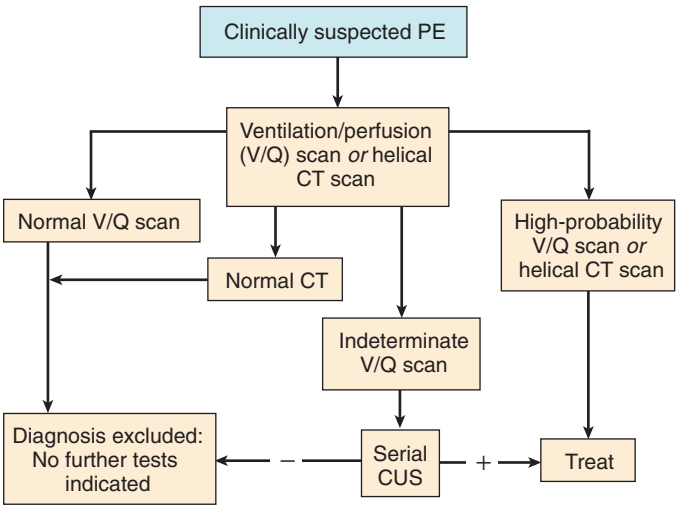

Figure 144-2 DIAGNOSTIC ALGORITHM FOR THE MANAGEMENT OF PATIENTS WITH SUSPECTED PULMONARY EMBOLISM (PE). *CT,* Computed tomography; *CUS,* compression ultrasound; *V/Q,* ventilation/perfusion.

DIAGNOSIS OF ACUTE RECURRENT VENOUS THROMBOEMBOLISM

The diagnosis of acute recurrent VTE is difficult to make because the clinical manifestations of recurrence are nonspecific. In addition, all of the validated diagnostic tests for acute VTE have limitations in this setting because the venous occlusion produced by the initial episode of venous thrombosis makes it difficult to identify new abnormalities.

The most appropriate diagnostic strategy for suspected recurrent DVT has yet to be determined. The patient's history may be helpful in determining the likelihood of recurrent thrombosis. Leg pain with ambulation and leg swelling that is relieved with overnight rest is typical of the postthrombotic syndrome. New clinically significant and persistent leg swelling, particularly if the symptoms do not abate overnight, is consistent with recurrent thrombosis and should prompt diagnostic evaluation. In patients taking vitamin K antagonists such as warfarin, it may also be useful to determine the international normalized ratio (INR) at the time of presentation and to assess the INR measurements in recent weeks. Warfarin is a very effective antithrombotic agent, and the risk of recurrent thrombosis in therapeutically anticoagulated patients irrespective of their symptoms is very low. Nevertheless, recurrent thrombosis despite therapeutic anticoagulation occasionally is seen in patients with cancer or those with antiphospholipid antibodies.

Many patients with a history of VTE will have a heightened level of concern about the risk of recurrent thrombosis. This heightened concern will lead these patients to seek testing for recurrent thrombosis even with incompatible symptoms. Such patients require careful clinical and radiologic evaluation. If there is no evidence of acute recurrence, they may require counseling and education about their condition.

To establish a diagnosis of recurrent DVT, one must demonstrate a new thrombus in a previously unaffected venous segment, either through lack of compressibility on ultrasonography or an intraluminal filling defect on venography. A normal venogram result rules out recurrence, and normal findings on ultrasound examination rule out proximal thrombus. A normal result on ultrasound study does not rule out recurrent calf vein thrombosis and requires that additional testing with serial ultrasonography be performed if this is suspected. If the lack of compressibility of the veins or an intraluminal filling defect with flow seen on Doppler ultrasound studies is visualized in the venous segment previously affected, these tests are not sufficiently reliable to either confirm or rule out acute thrombosis. In these cases, serial testing to detect extension may be useful. Alternately, if the patient had a follow-up ultrasound examination, comparison with previous imaging may be useful.

D-dimer–based testing strategies are very attractive in patients with suspected recurrence, because they may obviate the need for additional diagnostic testing. A quantitative D-dimer assay was evaluated in a prospective cohort of 300 patients with suspected recurrent DVT in which patients with a negative D-dimer had heparin withheld and patients with a positive D-dimer underwent compression ultrasonography.[62] This appears to be a safe strategy among symptomatic patients with suspected recurrence but must be validated with different D-dimer assays.

DIAGNOSIS OF THE POSTTHROMBOTIC SYNDROME

The clinical spectrum of the postthrombotic syndrome varies from a course that may mimic acute DVT to one of persistent leg pain that is worse at the end of the day and is associated with dependent edema; stasis pigmentation; and, in its most severe form, skin ulceration.[63] Rarely, patients may complain of venous claudication on walking.[64] When symptoms are acute or subacute in onset, a diagnosis of postthrombotic syndrome should be considered only after recurrent DVT has been excluded by objective testing. There is no single definitive diagnostic test for the postthrombotic syndrome, but a history of objectively documented DVT, appropriate clinical findings, and evidence of venous reflux or outflow obstruction on venous ultrasonography constitute sufficient evidence to make this diagnosis.

PROPHYLAXIS OF VENOUS THROMBOEMBOLISM

PE is a common preventable cause of death in hospitalized patients.[65] Hospitalized patients can be classified as having a low, moderate, or high risk for developing VTE. Effective prophylaxis is cost effective and is available for most high-risk groups.[66]

Low-Molecular-Weight Heparins and Fondaparinux

Low-molecular-weight heparins exert their anticoagulant effect by preferentially catalyzing the inactivation of factor Xa by antithrombin. When used in prophylactic doses once or twice daily, LMWH is an effective and safe agent for prophylaxis in medical and surgical patients. Anticoagulant monitoring is not required when used in prophylactic doses. It is as or more effective than standard low-dose UFH and warfarin in most patient populations.[67]

The anticoagulant effect of LMWH is mediated by a unique pentasaccharide sequence in the heparin molecule that binds antithrombin. The pentasaccharide moiety has been synthesized chemically as fondaparinux. Fondaparinux has been shown to be superior to LMWH for the prevention of VTE in patients undergoing hip fracture surgery. Extended use of fondaparinux in this patient population significantly reduces the risk of clinical VTE over an extended follow-up period.[68] Fondaparinux has also been shown in clinical trials to be as effective and safe as unfractionated intravenous heparin for the treatment of acute symptomatic PE,[69] as effective and safe as twice-daily LMWH for the treatment of DVT[70] and as effective as therapeutic dose enoxaparin in patients with unstable coronary syndromes. In this latter study, fondaparinux was also safer than enoxaparin.

Low-Dose Unfractionated Heparin

Low doses of UFH prevent thrombosis by antithrombin-mediated inhibition of thrombin, factor Xa, and other serine proteases. UFH is usually given subcutaneously at 5000 units 2 hours before surgery and continued postoperatively at 5000 units every 8 to 12 hours. Low-dose UFH prophylaxis does not require laboratory monitoring and is simple and convenient to administer. It is an acceptable option for moderate risk general surgical and medical patients, and it reduces the risk of VTE by 50% to 70%.[65,71-73] When used in these doses, UFH is both highly effective and associated with only a small increase in the risk of bleeding. Although low-dose UFH is effective in patients undergoing elective hip surgery and reduces the incidence of venous thrombosis by approximately 40%, it is less effective than other current prophylactic strategies and thus should not be used as the sole form of prophylaxis in such patients. Low-dose UFH has not been shown to be effective in patients with hip fractures or those undergoing major knee surgery. In addition, use of subcutaneous heparin may be associated with heparin induced thrombocytopenia, particularly in the postoperative period.

Vitamin K Antagonists

When administered in doses that prolong the prothrombin time to an INR of 2.0 to 3.0, vitamin K antagonists effectively prevent postoperative VTE in patients in all risk categories.[65,73] Vitamin K antagonists can be given preoperatively, at the time of surgery, or in the early postoperative period. The antithrombolytic effect of vitamin K antagonists is not achieved until the fourth or fifth day of administration. Nevertheless, when used in this fashion, vitamin K antagonists are effective in very high-risk patient groups.[74] Prophylaxis with vitamin K antagonists is relatively inconvenient, however, because careful laboratory monitoring using the INR is necessary.

Oral Direct Factor Xa or Thrombin Inhibitors for Orthopedic Thromboprophylaxis

Rivaroxaban is an oral direct factor Xa inhibitor with excellent bioavailability that has been studied in patients undergoing total knee or hip replacement surgery.[75-78] In a pooled analysis of these randomized trials, 10 mg/day of rivaroxaban was superior to enoxaparin for prevention of symptomatic VTE and all-cause mortality with similar major bleeding rates.[79] Although rivaroxaban has also been evaluated for prophylaxis in medically ill patients, its benefit-to-risk profile is less certain in this setting.

Dabigatran etexilate is an oral direct thrombin inhibitor that also has been used in patients undergoing total knee or hip replacement surgery. Dabigatran etexilate is a prodrug that is converted to the active agent dabigatran, which binds both free and clot-bound thrombin. In large clinical trials, once-daily dabigatran was noninferior to enoxaparin 40 mg once daily but was inferior when enoxaparin was dosed at 30 mg twice daily.[80-82]

Rivaroxaban is licensed in the United States, Europe, and Canada for orthopedic thromboprophylaxis. Although licensed in Europe and Canada, dabigatran etexilate is not approved in the United States for orthopedic thromboprophylaxis.

Intermittent Pneumatic Compression

Intermittent pneumatic compression of the legs enhances blood flow in the deep veins and increases systemic fibrinolytic activity.[65] Although few methodologically rigorous studies support the effectiveness of intermittent pneumatic compression for VTE prophylaxis, this modality has few clinically important side effects and is particularly useful in patients who have a high risk of bleeding. It also is frequently used, albeit with little supporting evidence, during the operative procedure in patients undergoing extended-duration surgery and in patients after trauma. Intermittent compression is the prophylactic measure of choice in selected patients undergoing neurosurgical procedures[83]; however, most of these patients should eventually receive pharmacologic thromboprophylaxis as well.[84]

Graduated Compression Stockings

Graduated compression stockings also reduce venous stasis in the legs and are effective for preventing postoperative VTE in low- and moderate-risk general surgical patients[72] and in medical or surgical patients with neurologic disorders, including paralysis of the lower limbs.[83] In surgical patients, the combination of graduated compression stockings and low-dose UFH is significantly more effective than low-dose UFH alone.[85,86] Use of graduated compression stockings alone, however, constitutes inadequate prophylaxis in patients undergoing surgery associated with a very high risk of thromboembolism.[87] Graduated compression stockings are inexpensive and should be considered for use in all high-risk surgical patients even if other forms of prophylaxis are used.

TREATMENT OF VENOUS THROMBOEMBOLISM

The goals of treatment for VTE are to prevent death from PE, reduce morbidity from the acute event, minimize development of post-thrombotic symptoms, and prevent chronic thromboembolic pulmonary hypertension. All of these goals can be achieved with adequate anticoagulant therapy. Use of thrombolytic therapy or surgical approaches are reserved for patients with severe disease or severe complications.

ANTICOAGULANT THERAPY FOR TREATMENT OF ACUTE VENOUS THROMBOEMBOLISM

The treatment of acute VTE currently involves administration of effective doses of a parenteral anticoagulant as soon as the diagnosis is confirmed (or if testing is delayed and the clinical likelihood of disease is moderate or high, before confirmation of the diagnosis).

Traditionally, patients with acute VTE were admitted to hospital and given intravenous UFH, administered to achieve a therapeutic activated partial thromboplastin time (aPTT). A vitamin K antagonist, typically warfarin, was then started and the heparin continued until the INR was more than 2.0 on two consecutive measurements. This treatment strategy remains a practice standard. However, the vast majority of patients with proximal DVT, calf vein thrombosis, and minimally symptomatic PE are now eligible to receive outpatient LMWH or fondaparinux treatment. These agents are preferred given the ease in administration and ability to be administered on an outpatient basis without the need for anticoagulant monitoring. Treatment with LMWH or fondaparinux involves administration of weight-adjusted, once- or twice-daily subcutaneous injections. If anticoagulant-related complications develop or if the patient is at the extremes of weight (<40 kg or >100 kg) or has severe renal insufficiency (creatinine clearance <30 ml/min), then the anticoagulant effect of the LMWH can be assessed using an anti(factor)-Xa assay. Typically, one would target a peak anti-Xa level of 0.5 to 1.0 unit/mL measured 4 hours after a subcutaneous injection of LMWH using a twice-daily dosing schedule. LMWH and fondaparinux do not have predictable effects on the aPTT and therefore cannot be monitored using this test.

Although increasingly less common, selected patients may be admitted to the hospital for intravenous UFH therapy. There is no evidence that UFH therapy is superior to LMWH in any clinical setting. Hence, intravenous UFH is typically reserved for patients with comorbid conditions that preclude outpatient treatment, including those with significantly symptomatic PE and patients at high risk of bleeding in whom rapid anticoagulant reversal may be necessary.[88] Patients with significant renal impairment are also typically treated with UFH because LMWH is predominantly renally eliminated and there is a risk of anticoagulant accumulation in these patients.

Unfractionated heparin therapy can be monitored using the activated clotting time, the aPTT, or by heparin assays that measure the ability of heparin to accelerate the inactivation of factor Xa or thrombin. It is important to give adequate doses of UFH at initial presentation because the risk of recurrent VTE is increased if insufficient doses are given. Accordingly, the aPTT should be maintained above a level equivalent to a heparin level of 0.3 unit/mL as determined by measuring the antifactor Xa activity. For most currently used aPTT reagents, this is equivalent to an aPTT ratio of 1.8 to 2.5 times the control value.[89] To monitor UFH given by continuous intravenous infusion, the aPTT should be measured 6 hours after the bolus dose so that it reflects the anticoagulant effects of the infusion. If twice-daily subcutaneous UFH is given, a mid-interval aPTT is typically measured 6 hours after the injection. However, UFH can also be used without laboratory monitoring; in a study of more than 700 patients, UFH was administered using a fixed, weight-adjusted dose without aPTT monitoring. The risk of bleeding and recurrent thrombosis was found to be similar to that seen in patients treated with twice-daily LMWH.[90]

After an initial course of parenteral therapy (heparin or fondaparinux), patients with VTE require ongoing anticoagulant therapy to prevent recurrence.[27,28] Patients with cancer-associated thrombosis may be treated with ongoing LMWH to decrease recurrence,[91] but most other patients should be transitioned to oral anticoagulant therapy. The most commonly used oral anticoagulants are the vitamin K antagonists, such as warfarin. In most cases, warfarin therapy can be initiated on the same day as the institution of the parenteral agent. The parenteral agent should be continued for at least 5 days and until the INR has been between 2.0 and 3.0 on 2 consecutive days.

Optimal warfarin dosing must consider the patient age and gender. An initial dose of 5 to 10 mg can be given to most individuals, and initial doses less than 5 mg should be used for elderly patients. Women generally require lower warfarin doses than men. The warfarin dose variability is also affected by variation in the genotypes of the cytochrome P450 CYP2C9 and the vitamin K epoxide reductase complex, VKORC1. These enzymes influence the rate of warfarin metabolism and sensitivity, respectively. Studies using warfarin genotyping to optimize warfarin dosing have yielded conflicting results, and further study along with economic evaluation is ongoing.

At the present time, novel oral anticoagulants are in development that do not require anticoagulant monitoring and have fewer interactions with food and drugs compared with warfarin. Dabigatran was noninferior to warfarin for the treatment of acute VTE. Rivaroxaban was also noninferior to combination treatment with enoxaparin and warfarin for treatment of DVT. However, neither of these agents is currently approved in the United States for treatment of VTE.

The optimal duration of oral anticoagulant therapy for treatment of VTE is unknown. Patients with a secondary thrombosis (provoked by a clear transient risk factor) are generally treated for 3 months. Patients with unprovoked (idiopathic) VTE should be treated for a minimum of 3 months, although consideration may be given for a longer duration of therapy. Patients with a persistent, major risk factor for recurrence and patients who prefer to decrease their thrombotic risk should receive warfarin for longer periods or indefinitely. At this time, there are no absolute predictors of recurrence, but recurrence appears to be more common in patients with an elevated D-dimer assay at or around the time of anticoagulant discontinuation, in the male sex, and possibly in patients with residual DVT seen on ultrasonography at the time of anticoagulant discontinuation.

INFERIOR VENA CAVA FILTER

Anticoagulants are effective in reducing mortality from PE.[92] However, some patients have relative or absolute contraindications to anticoagulant therapy. In these cases, there may be a role for inferior vena cava filters (see Chapter 145). These filters do not treat VTE but are used to prevent PE. In patients with a transient risk factor for bleeding, such as surgery for resection of a bowel tumor or active ulcer disease, insertion of a temporary inferior vena cava filter followed by its removal and subsequent therapeutic anticoagulation when the bleeding risk is diminished should be considered. Although not formally evaluated in randomized trials, this strategy likely reduces the initial risk of bleeding while eliminating the long-term increase in the risk of DVT associated with permanent caval interruption. In contrast, patients who have a persistent major risk factor for bleeding, such as angiodysplasia of the gastrointestinal tract, should be considered for insertion of a permanent inferior vena cava filter because the mortality rate associated with major bleeding occurring during therapeutic anticoagulation is approximately 20%. This procedure is associated with a significant risk of immediate worsening of leg symptoms because of blockage of the inferior vena cava by thrombus and a long-term increase in the risk of recurrent DVT.

THROMBOLYTIC THERAPY FOR MASSIVE PULMONARY EMBOLISM

Thrombolytic therapy with streptokinase, urokinase, or t-PA is more effective than UFH alone in correcting the angiographic defects

produced by PE[92] and may be better than UFH in preventing death in patients with massive PE associated with shock.[93,94] Based on these findings, thrombolytic therapy is the treatment of choice for patients with massive PE associated with cardiovascular collapse and in those with underlying cardiac or pulmonary disease, in whom even a small or moderate-sized embolus may be life threatening.

Bleeding occurs more frequently with thrombolytic therapy than with UFH.[92,95] The risk of hemorrhage increases with the duration of thrombolytic infusion and usually occurs at a site of previous surgery or trauma. Intracranial hemorrhage occurs in approximately 1% of patients at risk, approximately twice as frequently as with UFH treatment.

THROMBOENDARTERECTOMY FOR PULMONARY EMBOLISM

Thromboendarterectomy is effective in selected cases of chronic thromboembolic pulmonary hypertension with proximal pulmonary arterial obstruction.[96] Urgent pulmonary embolectomy is usually reserved for patients with a saddle embolism lodged in the main pulmonary artery or for those with massive embolism whose blood pressure cannot be maintained despite thrombolytic therapy and vasopressor agents.[92] Although this procedure can be successfully performed by experienced surgical teams, in inexperienced hands, it is associated with high complication and mortality rates. Patients with repeated episodes of PE and significant chronic pulmonary hypertension with right ventricular compromise should be anticoagulated and monitored. If pulmonary pressures do not decrease, patients should be evaluated for surgical fitness. If deemed necessary, thromboendarterectomy should be carried out in centers with expertise with optimal perioperative management, within which the likelihood of success of the procedure is high.[96]

CHAPTER 145

MECHANICAL INTERVENTIONS IN ARTERIAL AND VENOUS THROMBOSIS

Steven Sauk and Suresh Vedantham

Arterial and venous thromboses are common medical conditions that are associated with significant morbidity. Patients who suffer from acute occlusions of the peripheral arteries may present with ischemic extremities, culminating in limb loss or death if left untreated. Those who suffer from venous thrombosis are at significant risk not only for pulmonary embolism (PE), but also for a chronic condition known as the postthrombotic syndrome (PTS), which can cause significant impairment of patients' quality of life (QOL).

For many patients with symptomatic arterial or venous occlusions, surgical therapies are required in addition to standard medical treatments to provide optimal patient outcomes. Spurred by advances in vascular imaging and catheter/device technology and driven by the clinical needs of the large number of vascular patients with concomitant comorbidities, many patients are now referred for nonsurgical, imaging-guided endovascular interventions to eliminate thrombi and to treat associated vascular lesions. In this chapter, we discuss the use of catheter-based interventions in the management of arterial and venous thromboses.

OVERVIEW OF CATHETER-BASED THROMBOLYTIC INTERVENTIONS

Systemic thrombolysis, which refers to the dissolution of thrombus via the administration of a fibrinolytic drug into an intravenous line distant from the affected site, can be a valuable treatment option for acute myocardial infarction (MI), massive PE, and acute ischemic stroke. A primary advantage of the systemic administration route is the ability to rapidly initiate therapy in almost any clinical setting, without the need for specialized technical expertise or hospital resources. However, only a fraction of systemically administered drug reaches the target vessel. This problem is compounded when there is complete occlusion of blood flow in the target vessel such that access of the fibrinolytic drug to the interior of the thrombus is precluded. For acute MI and stroke, this limitation is overcome by the use of relatively high concentrations of fibrinolytic drugs (e.g., 50-100 mg of recombinant tissue plasminogen activator [rt-PA]) and the ability of arterial pulsations to force sufficient amounts of the drug into the fresh thrombus that occludes a small (2-4 mm) coronary or cerebral artery to effect fibrinolysis. However, with these high doses of fibrinolytic drugs, there is a small, but significantly increased risk for major bleeding, a price that physicians are willing to pay given the potentially fatal consequences of ongoing vascular occlusion in these critical sites.

For occlusions in the peripheral arteries and veins, however, systemic fibrinolysis is not sufficiently effective to justify the attendant risks, presumably because of the larger vessel size, greater thrombus burden, and the presence of mature thrombus that is less susceptible to dissolution. For these reasons, catheter-directed fibrinolysis and mechanical methods for thrombus extraction and dissolution have been developed.

Catheter-Directed Intrathrombus Thrombolysis

Catheter-directed intrathrombus thrombolysis (CDT) refers to the infusion of a fibrinolytic drug directly into the thrombosed vessel via a catheter that has been inserted into that vessel using imaging guidance.[1] The rationale for CDT is to improve the efficacy of thrombus dissolution by achieving a higher intrathrombus concentration of fibrinolytic drug, and to reduce the risk for hemorrhage by enabling the use of lower total fibrinolytic drug doses than those required for systemic fibrinolysis. Although several catheters and devices have been approved by the Food and Drug Administration (FDA) for this purpose, none of the currently available fibrinolytic drugs is FDA-approved for the specific indication of peripheral arterial or venous thrombosis.

Although the procedural details are beyond the scope of this chapter, the principles of CDT are reviewed here[2,3] (Fig. 145-1). First, a vascular access site is selected based on the thrombus location and extent, and needle access into the vessel is obtained. With ultrasound-guided venipuncture, access site bleeding is rare. Under fluoroscopic guidance, the needle is exchanged over a guidewire for an angiographic catheter, and iodinated contrast is injected to delineate the location, extent, and morphology of the thrombus and the status of other relevant vessels in the limb. The angiographic catheter is then exchanged for a specially designed infusion catheter with multiple side holes (akin to a soaking garden hose) that is positioned so that the side holes are embedded within the thrombus-containing vascular segment. Fibrinolytic drug is then infused. The drugs and doses commonly used for this purpose include rt-PA (0.5-1.0 mg/hr), reteplase (0.25-0.75 units/hr), and tenecteplase (0.25-0.50 mg/hr).[4,5] The procedure is done under conscious sedation and with local anesthesia, and the heart rate, blood pressure, and oxygen saturation are continuously monitored.

Patients are then transferred to an observation unit, usually an intensive care or step-down unit, for monitoring during the fibrinolytic drug infusion. Typically, a concomitant infusion of unfractionated heparin at subtherapeutic doses is administered, and the hemoglobin, partial thromboplastin time (PTT), and in some centers, the fibrinogen level are determined every 6 to 8 hours while the fibrinolytic drug is given. Patients are monitored closely for evidence of bleeding and for changes in limb status, and the drug infusion rate is adjusted (or stopped entirely) as necessary. After 6 to 18 hours, patients return to the procedure room for a follow-up venogram or angiogram to assess the extent of thrombus dissolution. The infusion catheter may be repositioned and the infusion continued if there is residual thrombus. Once thrombolysis is nearly complete, the fibrinolytic drug infusion is stopped, and based on the results of the venogram or angiogram, a decision is made as to whether adjunctive treatment with balloon angioplasty or stent placement is needed—if so, this is performed, usually through the same vascular access site during the same procedure session. The catheter and sheath are then removed, and systemic anticoagulation at fully therapeutic levels is reinstituted. The treated limb is closely monitored for improvement in pain, perfusion abnormalities (arterial), and/or swelling (venous).

Although few changes have been made to the CDT technique over the past 25 years, there has been a switch from biologically derived fibrinolytic drugs (streptokinase and urokinase) to recombinant drugs that are less allergenic and have greater affinity for fibrin. Recently, a multi–side-hole catheter (the Ekosonic Mach 4e catheter) that not only enables drug infusion, but also emits low-power

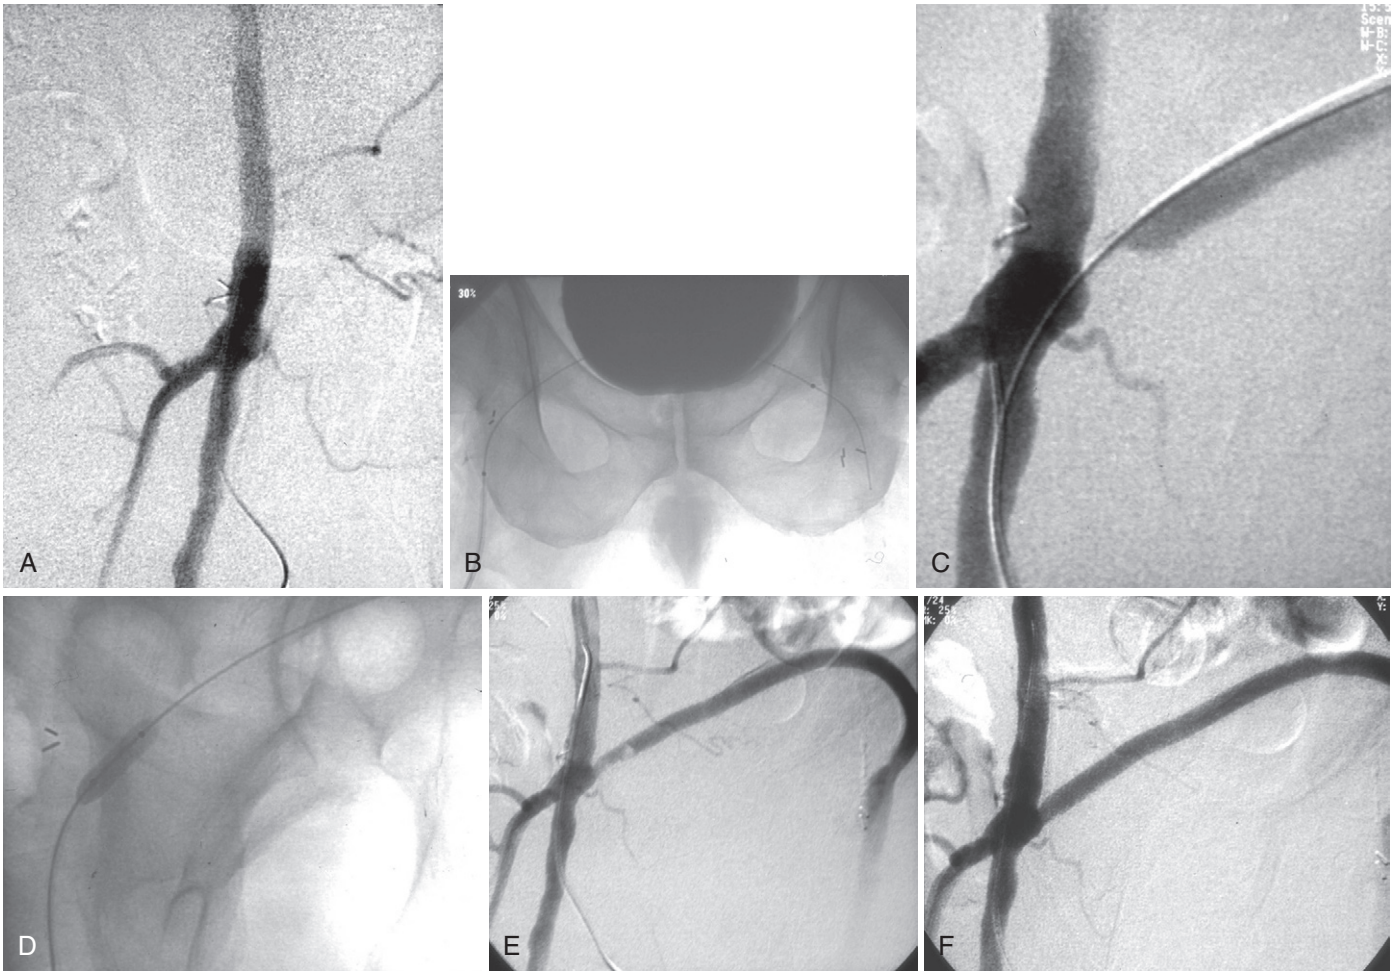

Figure 145-1 A 67-YEAR-OLD MAN WITH A CHRONIC LEFT ILIAC ARTERY OCCLUSION AND A RIGHT-TO-LEFT FEMORAL–FEMORAL ARTERIAL BYPASS GRAFT PRESENTS WITH LEFT FOOT PAIN AND PULSELESSNESS. **A,** Digital subtraction arteriography reveals patency of the right iliac artery, but only a "stump" of the bypass graft is seen, consistent with graft thrombosis. **B,** The lowermost aspect of the right common femoral artery was accessed, and a multi–side-hole infusion catheter was positioned across the occluded graft. The radiopaque markers show the infusion zone. An infusion of rt-PA was given at 0.5 mg/hr through this catheter. The patient received heparin (500 units/hr) through a peripheral intravenous catheter. **C,** After 16 hours of thrombolysis, a repeat arteriogram reveals successful thrombus removal with residual tight focal stenosis at the proximal graft anastomosis. **D,** The stenosis was subjected to angioplasty using a 6-mm balloon. **E,** Repeat arteriogram shows improvement in the stenosis, but small thrombi are evident within the graft. **F,** After use of the AngioJet Rheolytic Thrombectomy System to aspirate residual thrombus, the graft is widely patent. Subsequent physical examination revealed good pedal pulses and capillary refill, consistent with successful reperfusion of the limb.

ultrasound energy to ostensibly loosen fibrin strands and permit more rapid intrathrombus drug dispersion has been introduced.[6] Although limited evidence suggests that this catheter permits successful thrombolysis with reasonably good treatment times (16-21 hours), conclusive evidence of improved patient outcomes is lacking.

Variation on a Theme—Percutaneous Mechanical Thrombectomy

Hemorrhagic complications are the Achilles' heel of currently available thrombolytic agents. To reduce exposure to these drugs, specialized catheters, known as percutaneous mechanical thrombectomy (PMT) devices, have been developed. PMT is the use of a percutaneous catheter-based device that contributes to thrombus removal via thrombus fragmentation, maceration, and/or aspiration.[1] Although the devices were originally developed to supplant thrombolytic drugs, none of the available PMT devices enables safe, successful clot removal when used as a stand-alone treatment.[5] Consequently, fibrinolytic drugs are used in conjunction with PMT, except in situations in which absolute contraindications to the use of fibrinolytic drugs exist and no other treatment options are available.

Variations on a Theme—Pharmacomechanical Catheter-Directed Thrombolysis

Pharmacomechanical catheter-directed thrombolysis (PCDT) refers to thrombus dissolution via the combined use of CDT and PMT devices.[1] The rationale for utilizing both modalities is twofold. First, fibrinolytic drugs given via CDT soften the thrombus, rendering it more susceptible to mechanical fragmentation and removal with PMT, while also dissolving thrombus fragments that may otherwise embolize. Second, PMT devices macerate the thrombus, enhance dispersion of the fibrinolytic drug, and can accelerate pharmacologic thrombolysis. Although a broad range of PCDT techniques have been used, these techniques largely fall into two general categories: (1) "first-generation" PCDT techniques incorporate PMT devices to assist traditional CDT—either a PMT device is first used to de-bulk thrombus before starting the CDT infusion, or a PMT device is used after initial CDT to aspirate and/or macerate residual thrombus; (2) "single-session" PCDT techniques use PMT devices that can rapidly disperse the thrombolytic drug within the thrombus to enable the entire clot removal treatment to be completed in a single on-table procedure session, thereby obviating the need for an overnight thrombolytic infusion with the required ICU monitoring.

Single-session PCDT techniques have attracted considerable interest. Two currently available devices can be used for single-session PCDT. The AngioJet Rheolytic Thrombectomy System uses high-velocity saline jets to fracture the thrombus through a combination of rapid fluid streaming and hydrodynamic forces. Based on the Bernoulli principle of low pressure, these jets create a localized negative pressure zone at the catheter tip, enabling clot aspiration. With the "Powerpulse" PCDT technique, the Angiojet is first used to deliver a thrombolytic drug into the thrombus via a powerful pulse-spray injection.[7] After a 20- to 30-minute dwell time, the AngioJet is then used to aspirate and remove the softened thrombus. The "Isolated Thrombolysis" technique refers to the use of the Trellis Peripheral Infusion System to provide single-session PCDT[8] (Fig. 145-2). The Trellis device is composed of a multilumen catheter with two balloons, which when inflated, effectively isolate a thrombus-containing treatment zone from the remainder of the venous circulation. After the device is advanced across the venous thrombus, the occluding balloons are inflated and a thrombolytic drug is injected into the thrombus via side holes in the catheter. A sinusoidal wire within the catheter oscillates to disperse the drug within the thrombus, after which liquefied thrombotic debris can be aspirated through a port in the catheter. Both single-session PCDT techniques feature rapid intrathrombus drug dispersion that promotes faster thrombolysis, thereby reducing patient exposure to the fibrinolytic drug. Because the mechanical manipulation can induce thrombus fragmentation and embolization, these methods are best suited for venous applications.

Mechanical Interventions in Peripheral Arterial Occlusion

Acute peripheral arterial occlusion (PAO) is associated with high rates of morbidity and mortality. Up to 15% to 20% of patients with chronic peripheral arterial disease will develop acute exacerbation of symptoms (acute limb ischemia), usually due to thrombosis of the involved artery; these patients are at high risk for limb loss. Even with treatment, the 30-day mortality rate of acute arterial thrombosis is approximately 15%, and the amputation rate ranges from 10% to 30%.[9]

Rationale, Benefits, and Risks Associated With CDT for PAO

The traditional treatment for acute limb ischemia is open surgery. However, the emergent nature of these procedures and the characteristics of affected patients, who tend to have high rates of concomitant coronary and cerebrovascular disease, have contributed to significant rates of perioperative complications and death. By dissolving platelet-fibrin aggregates in the microcirculation and thrombi in collateral vessels, CDT allows rapid but gradual reperfusion of the distal limb, thereby minimizing the risk for reperfusion complications and compartment syndrome.[4] CDT enables both rapid restoration of arterial blood flow to the ischemic limb and unmasking of arterial stenotic or occlusive lesions that require treatment. Because many such lesions can be treated with endovascular techniques, such as balloon angioplasty or stent placement, CDT allows many patients to avoid the risks and inconveniences of open surgery. When surgery is required, a more limited procedure can often be performed on an elective basis in a well-prepared patient, with reduced rates of complications and death.

The major complication of CDT is bleeding.[10] In the setting of PAO, the incidence of CDT-related hemorrhagic stroke is approximately 1%. The rate of major hemorrhage, defined by hypotension, need for surgical therapy, or need for blood transfusion, is approximately 5%, with minor hemorrhage (e.g., local hematoma) occurring in 15% of patients. In modern practice, the use of subtherapeutic doses of heparin during thrombolysis may help to minimize bleeding complications.[11] Distal embolization of thrombus fragments occurs in about 5% of cases; most of these resolve with continued lytic

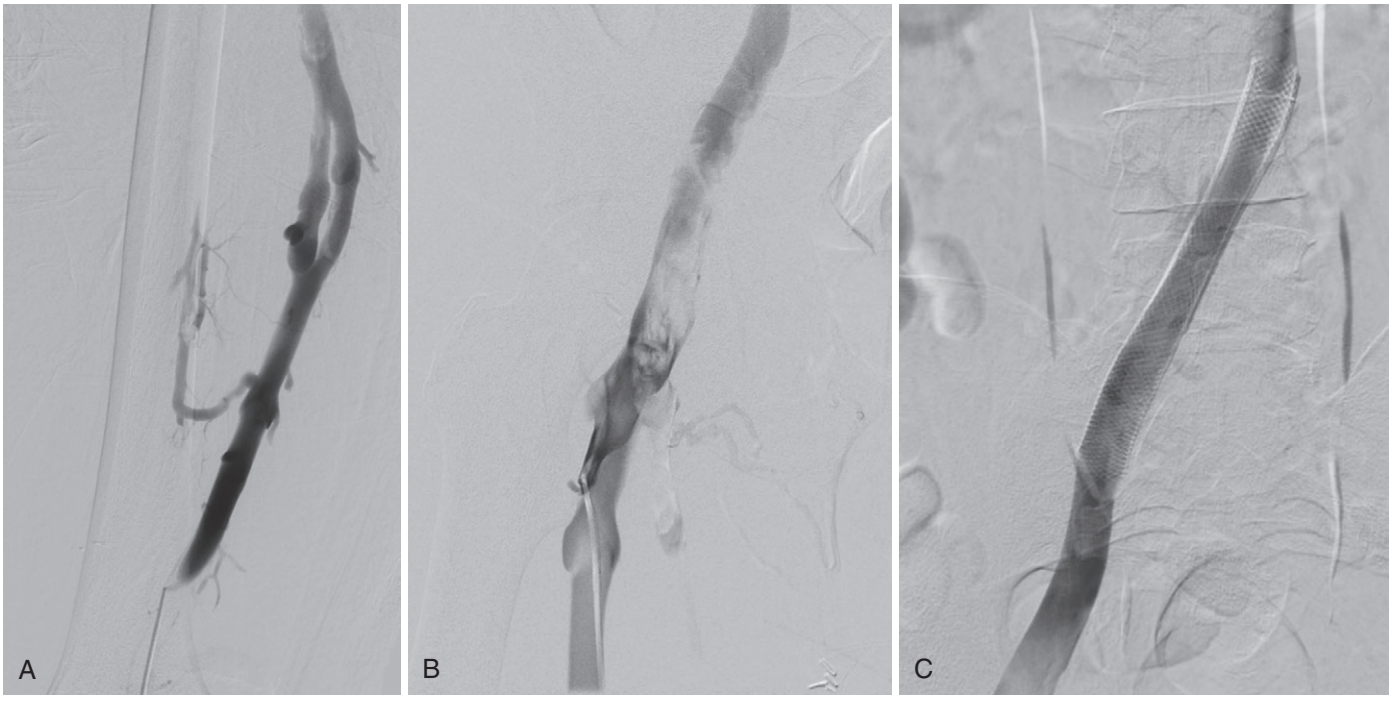

Figure 145-2 A 35-YEAR-OLD MAN PRESENTS WITH A 3-DAY HISTORY OF SEVERE LEFT LOWER EXTREMITY PAIN AND SWELLING. **A,** Digital subtraction venogram from a left popliteal vein approach shows patency of the lower part of the femoral vein with a short segment of duplication, a normal variant. **B,** The left common femoral and iliac veins have large globular filling defects, consistent with acute iliofemoral DVT. **C,** The Trellis device was used to deliver and disperse 10 mg of rt-PA into the thrombus. After balloon maceration of the thrombus and subsequent placement of two 12-mm stents to treat stenosis of the left common iliac vein, the left common femoral vein and iliac vein are seen to be widely patent. The pain and swelling resolved within a few days.

therapy. However, worsening ischemia can occur and generally requires percutaneous thrombus aspiration or operative intervention if the condition does not improve with thrombolysis within a few hours. Compartment syndrome, a complication that results from rapid reperfusion of the ischemic limb, occurs in 2% of patients. Death occurs in less than 1% of patients, usually in the setting of intracranial or abdominal hemorrhage, or reperfusion syndrome. Complications of CDT, which usually are minor, can also be related to intraarterial catheter insertion. Catheter-related trauma, resulting in mural dissection, puncture-site pseudoaneurysm, and/or major hematoma occurs in 1% to 2% of patients.

Randomized Trials—CDT Versus Surgery for Arterial Thrombosis

Three randomized controlled trials compared clinical outcomes in patients with acute PAO who were randomized to receive either CDT or surgical intervention. The Rochester Trial randomized 114 patients presenting with acute limb ischemia to catheter-directed urokinase infusion or surgery.[12] Although there was no difference in limb salvage rates at 1 year, mortality at 1 year was significantly lower with urokinase than with surgery. However, there was more bleeding with CDT than with surgery.

The STILE (surgery versus thrombolysis for ischemia of the lower extremity) trial included 393 patients who either underwent CDT with urokinase or rt-PA or surgery.[13] In patients with acute ischemia, CDT was associated with significantly fewer amputations, increased amputation-free survival at 1 year, and a shorter hospital stay. However, in those with chronic ischemia, surgery was associated with fewer amputations and improved amputation-free survival (Table 145-1). In a subgroup analysis, the patients with acute bypass graft occlusions had a significantly lower rate of amputations compared with those patients who underwent surgery. These data suggest that patients with acute bypass occlusion may derive the greatest benefit from CDT.

The TOPAS (thrombolysis or peripheral arterial surgery) trial randomized 544 patients with acute limb ischemia to CDT with recombinant urokinase or to surgery.[11] No difference in amputation-free survival was evident at 1 year. However, CDT was associated with more bleeding complications, including a 1.6% rate of intracranial hemorrhage.

In summary, the results of these three trials suggest that CDT reduces the need for amputation and surgical intervention in patients with acute limb ischemia, particularly those with acute bypass graft occlusion. However, the risk for bleeding is higher with CDT than with surgery. Although outcomes in patients with acute limb ischemia are better with CDT, surgery is recommended for those with chronic ischemia.

PMT, PCDT, and Ultrasound-Assisted CDT for Arterial Thrombosis

A paucity of data exists concerning the relative effectiveness and safety of newer thrombolytic techniques for PAO. The AngioJet device is FDA-approved for peripheral arterial thrombus removal and is routinely utilized as an adjunct to CDT.[14] Limited data are available related to the safety and efficacy of the AngioJet, Trellis, and Ekosonic devices for the treatment of PAO. Aside from bleeding, the major complications associated with PMT and PCDT are distal embolization and local vascular injury (i.e., dissection or rupture).

Summary: Indications and Contraindications for Thrombolytic Therapy in PAO

The use of arterial CDT should be individualized. Reasonable candidates include those with (1) acute (<14 days) thrombosis of a previously patent bypass graft or native artery; (2) acute embolus in a vessel not readily accessible to surgical embolectomy; (3) acute thrombosis of a popliteal artery aneurysm resulting in severe ischemia when all distal run-off vessels are also thrombosed; and (4) acute arterial thromboembolic occlusions in patients who are poor surgical candidates.[11,15,16] The clinical status of PAO patients should be categorized using the Rutherford classification scheme (Table 145-2). Patients

Table 145-1 Clinical Outcomes in Patients With Acute or Chronic Limb Ischemia Treated by Catheter-Directed Thrombolysis or Surgery in the STILE Trial

	Acute Ischemia (≤14 days), n = *112*			*Chronic Ischemia (>14 days),* n = *266*		
	Surgery (%)	**Lysis (%)**	**P-value**	**Surgery (%)**	**Lysis (%)**	**P-value**

with Rutherford category I, category IIa, and in specific cases, category IIb disease are potential candidates for CDT. In patients with irreversible limb ischemia, mild to moderate ischemia with claudication, early postoperative bypass graft thrombosis, or large vessel thrombi that are easily accessible by surgery, open surgery is preferred over CDT. Absolute and relative contraindications to CDT are outlined in Table 145-3.

Mechanical Interventions in Deep Vein Thrombosis

Venous thromboembolism (VTE) occurs in 350,000 to 600,000 persons per year in the United States alone, of which more than 250,000 cases represent a first-episode of deep vein thrombosis (DVT). The management of DVT has traditionally been anchored in a longstanding view of the disease as an "acute" condition involving an initial period of high risk for PE (which is estimated to kill over 100,000 persons in the United States each year), followed by a steadily diminishing risk over time that ultimately permits discontinuation of anticoagulant therapy in most patients. In recent years, there is better appreciation of the long-term impact of DVT in terms of the risk for recurrence, particularly in those with unprovoked VTE, and the high incidence of PTS in patients with extensive DVT.

For most patients, initial DVT therapy consists of administration of a parenteral anticoagulant drug (unfractionated heparin, low-molecular-weight heparin [LMWH], or fondaparinux) with subsequent transition to long-term oral vitamin K antagonist therapy for at least 3 months, with the duration of therapy dependent on the presence or absence of ongoing risk factors for recurrence.[17] The preferred initial approach for most patients with cancer-related DVT is LMWH monotherapy for at least 3 to 6 months. The therapeutic goals of anticoagulant therapy are to prevent symptomatic and fatal PE, thrombus progression, and late recurrent DVT. Currently available anticoagulants are effective in achieving these goals in most patients. In general, during the first year after discontinuation of anticoagulant therapy, recurrent VTE events occur in 3% to 5% of patients whose DVT episode was provoked by a major reversible risk factor and in 10% to 15% of patients with unprovoked/idiopathic DVT or cancer-related DVT.

Table 145-3 Contraindications to Thrombolytic Therapy

ABSOLUTE CONTRAINDICATIONS
Active bleeding
History of stroke within the previous 3 months
Neurosurgery (intracranial, spinal) within the previous 3 months
Intracranial trauma within the previous 3 months
RELATIVE CONTRAINDICATIONS
Recent (<7-10 days) major surgery, trauma, CPR, obstetrical delivery, or cataract surgery
Recent (<7-10 days) major invasive procedure or puncture of uncompressible vessel
Recent (<3 months) internal eye surgery or hemorrhagic retinopathy
Acute gastroduodenal ulcer or recent (<7-10 days) gastrointestinal bleeding
Intracranial neoplasm, arteriovenous malformation, aneurysm, or other lesion
Uncontrolled hypertension (systolic >180 mm Hg or diastolic >110 mm Hg)
Hepatic failure, particularly in cases with coagulopathy
Bacterial endocarditis or septic thrombophlebitis
Pregnancy
Severe anemia or thrombocytopenia

Rationale, Benefits, and Risks Associated With CDT for DVT

PTS develops in 20% to 50% of patients after a first episode of lower extremity DVT.[18] The symptoms and signs of PTS include chronic aching, swelling, fatigue, heaviness, edema, hyperpigmentation, and/or subcutaneous fibrosis in the affected limb. In severe cases, patients may experience short-distance venous claudication and venous leg ulcers—both of which limit ambulation and the ability to work and perform the activities of daily living. Consequently, PTS reduces health-related QOL. In fact, in a recent large prospective cohort study, the presence and severity of PTS were the leading determinants of QOL 2 years after an initial lower extremity DVT.[19] PTS also occurs with moderate frequency in patients with upper extremity DVT, particularly those who present with axillosubclavian involvement in the dominant arm. The management of PTS results in major economic costs to patients and society because of the direct medical costs of caring for its clinical sequelae (e.g., venous ulcers) and the indirect costs of work disability.

The pathogenesis of PTS is complex and incompletely understood. Inflammatory mediators, growth factors, extracellular matrix components, blood-borne elements, and endothelial cell factors contribute to the inflammatory response to DVT, which influences thrombus resolution, organization, and subsequent venous wall injury.[20] Even with anticoagulant therapy, incomplete clearance of thrombus is common, and residual thrombus often blocks venous blood flow. In addition, venous valves may be damaged, resulting in valvular reflux. The combination of valvular reflux and obstruction causes ambulatory venous hypertension, which leads to edema, tissue hypoxia and injury, progressive calf pump dysfunction, subcutaneous fibrosis, and skin ulceration. Therefore it is logical to postulate that rapid thrombus elimination and restoration of deep venous flow may prevent these untoward physiologic effects and preserve long-term venous function.

In support of this "open vein" hypothesis are studies that have observed a strong correlation between the amount of residual thrombus after a course of anticoagulant therapy and the subsequent incidence of recurrent venous thromboembolism. Moreover, data from a number of small randomized trials suggest that systemic thrombolysis and contemporary surgical venous thrombectomy are associated with improved long-term venous patency, preservation of venous valvular function, and reduced PTS compared with anticoagulation alone. However, these studies are small and have methodologic limitations. For patients with DVT, CDT is performed using the same procedures as those used for arterial thrombosis. Ultrasound-guided access to an extremity vein, usually the popliteal vein for the lower extremity, is obtained.[3] A venogram is performed, and the CDT or PCDT methods described earlier are used to remove the thrombus. After clot lysis, venography is performed to evaluate the underlying vein. Any residual stenosis is then treated with angioplasty or stenting. In general, the use of stents after DVT thrombolysis is optimally limited to the iliac vein, although it is sometimes necessary to extend contiguous stents into the common femoral vein. Patients with femoral vein stenosis, or isolated common femoral vein lesions that do not extend into the iliac vein, are best treated with angioplasty. Axillosubclavian venous thrombosis of known cause (e.g., previous central venous catheter) is amenable to balloon angioplasty if there is underlying stenosis. In patients with primary axillosubclavian venous thrombosis ("effort thrombosis"), stenosis of the subclavian vein is typically identified and is best treated with surgical thoracic outlet decompression rather than aggressive balloon angioplasty or stenting. With rare exceptions, stent placement in the subclavian vein is contraindicated because of the high frequency of stent fractures.

In a 473-patient multicenter registry, the use of CDT resulted in successful clot lysis in more than 80% of patients with acute proximal DVT.[21] However, major bleeding was observed in 11.4% of patients, mostly access site bleeding. Intracranial bleeding was observed in 0.4% of patients, and fatal PE occurred in 0.2% of patients. Adjunctive CDT or PCDT plus anticoagulant therapy has been compared

with anticoagulant therapy alone. In a case-control study that included 68 patients with acute iliofemoral DVT who underwent technically successful CDT, Comerota and colleagues reported fewer PTS symptoms and improved QOL at 16-month follow-up compared with a similar group of 30 patients who received anticoagulant therapy alone.[22] In a nonrandomized study, AbuRahma and colleagues[23] reported higher rates of symptom resolution at 5 years in iliofemoral DVT patients treated with CDT than in controls (78% versus 30%, $p = 0.0015$). A small randomized trial reported a higher rate of normal venous function with CDT at 6 months than with anticoagulation alone (72% versus 12%, $p < 0.001$) and less valvular reflux (11% versus 41%, $p = 0.04$).[24] Finally, a preliminary report from an ongoing Norwegian multicenter randomized trial[25] reported a lower rate of late venous obstruction with CDT compared with anticoagulation alone (64% versus 36%, $p < 0.001$). These studies highlight the potential for CDT to restore venous patency in patients with extensive DVT, as well as the risks and inconveniences of such treatment. However, these studies have limitations, including surrogate outcome measures, inclusion of only a single-center, small sample size, and/or nonrandomized design. Advances in CDT techniques, such as routine ultrasound-guided venipuncture and the use of PCDT to accelerate treatment and limit fibrinolytic drug exposure, have the potential to reduce bleeding. As a result, more recent studies with low-dose rt-PA report major bleeding rates of 3% to 4%.[25] Therefore contemporary methods of PCDT have been integrated into pivotal multicenter randomized trials, including the ongoing NIH-sponsored ATTRACT (acute venous thrombosis: thrombus removal with adjunctive catheter-directed thrombolysis) trial.

Acute Iliofemoral DVT as a High-Risk Condition

It is important for physicians to recognize the range of clinical presentations of proximal DVT. The extent of thrombosis is an important predictor of clinical course and long-term outcome with anticoagulant therapy. In particular, with femoral vein thrombosis, the primary collateral route by which blood leaves the limb (and by which the venous obstruction is decompressed) is the deep (profunda) femoral vein, which empties into the common femoral vein in the groin. Consequently, thrombosis above the entry point of the deep femoral vein (i.e., in or above the common femoral vein) causes more severe outflow obstruction, which often results in more leg swelling and pain and a higher incidence of late clinical sequelae.

Iliofemoral DVT is defined as DVT involving the iliac vein and/or common femoral vein, with or without involvement of other lower extremity veins.[1] Although physicians typically classify DVT as either distal or proximal because the risk for PE is higher with proximal DVT, patients with iliofemoral DVT have poorer clinical outcomes than patients with less extensive proximal DVT. In a prospective study of 1149 DVT patients, involvement of the common femoral vein and/or iliac vein portended a 2.4-fold increased risk for recurrent VTE during 3 months follow-up.[26] Likewise, in a large prospective cohort study, patients with iliofemoral DVT had 2 to 3 times more severe PTS than those with less extensive DVT.[18] Hence it is important to view iliofemoral DVT as a high-risk condition and to ensure the utilization of evidence-based PTS prevention measures, including therapeutic anticoagulation of appropriate intensity and duration and the use of elastic compression stockings. These patients are readily identified because they usually present with swelling of the entire limb and most have compression ultrasound evidence of thrombus in the common femoral vein.

Patients with acute (symptom duration ≤4 days) iliofemoral DVT who are not at increased risk for bleeding are the best candidates for CDT and PCDT.[17] In a large registry of DVT patients receiving CDT, patients with acute iliofemoral DVT were the most likely group to experience successful removal of thrombus, and many of the small studies supporting use of thrombus removal for DVT were performed in patients with iliofemoral DVT.[21-23] There are no well-designed prospective studies of CDT for treatment of upper extremity DVT; generally, such treatment is restricted to symptomatic patients with axillosubclavian thrombosis of recent onset.

Summary: Indications and Contraindications for CDT in DVT

The lack of data to establish the utility and proper indications for CDT in DVT patients does not absolve physicians of their responsibility to ensure that the long-term risks of PTS are carefully considered when crafting an individualized treatment strategy for DVT patients. The strategy should incorporate a high degree of confidence in anticoagulation drugs and compression therapy, a familiarity with the available (albeit imperfect) data that suggest that CDT is reasonable for selected DVT patients, and an individualized assessment of the clinical DVT severity, extent of thrombosis, comorbidities, and personal preferences of the patient.

Patients who do not meet a clinical threshold justifying the use of CDT include those with asymptomatic DVT or DVT isolated to the calf (because the risk for PTS is relatively low in these groups) and patients with chronic femoropopliteal DVT (because studies have shown that organized thrombus is not susceptible to thrombolytic drugs).[21]

The most important safety factor to consider in a patient being evaluated for DVT thrombolysis is the risk for major bleeding. Factors associated with an increased risk for bleeding include ongoing or recent bleeding; recent major surgery, trauma, pregnancy, obstetrical delivery, or cardiopulmonary resuscitation; or the presence of lesions in critical areas such as the central nervous system that may bleed. Because CDT involves the administration of iodinated contrast material for venography, renal function is also an important consideration, as are life expectancy, baseline ambulatory capacity, and comorbidities.[5,27] Patients with limited long-term mobility or those with a life expectancy of less than 6 months are unlikely to benefit from aggressive therapy to prevent PTS. Comorbidities that increase procedure risks, such as respiratory compromise that limits the use of sedation, may also render CDT less attractive.

Urgent endovascular thrombolysis is indicated to prevent life-, limb-, or organ-threatening complications of acute DVT in situations such as phlegmasia cerulea dolens or extensive inferior vena cava (IVC) thrombosis (especially with suprarenal extension, which may lead to fatal PE or acute renal failure). The use of endovascular thrombolysis in these situations is justifiable when other treatment options are lacking. In contrast, significant uncertainty exists regarding the appropriate indications for nonurgent CDT for the treatment of DVT. In 2008, guidelines from the American College of Chest Physicians and the Society of Interventional Radiology suggested that CDT/PCDT may be appropriate as an adjunct to anticoagulant therapy for selected patients with major symptomatic axillosubclavian DVT or extensive proximal lower extremity DVT, such as those with acute iliofemoral DVT, who have a low risk for bleeding and a long life expectancy.[5,17] The 2011 guidelines from the American Heart Association concurred and suggest that CDT also may be reasonable for patients with progression of DVT symptoms or rapid thrombus extension despite initial anticoagulation.[27]

Treatment of Established Postthrombotic Syndrome

Patients with established PTS suffer major symptoms that significantly impair their ability to conduct their daily activities and to enjoy a normal QOL. Unfortunately, once PTS has developed, no treatments have consistently been shown to be effective. Despite limited evidence of benefit, elastic compression stockings are often used because of their low risk and ready availability. Low-dose diuretics may be useful to reduce edema. Patients with venous ulcers can be treated with pentoxifylline, multilayer compression bandaging,

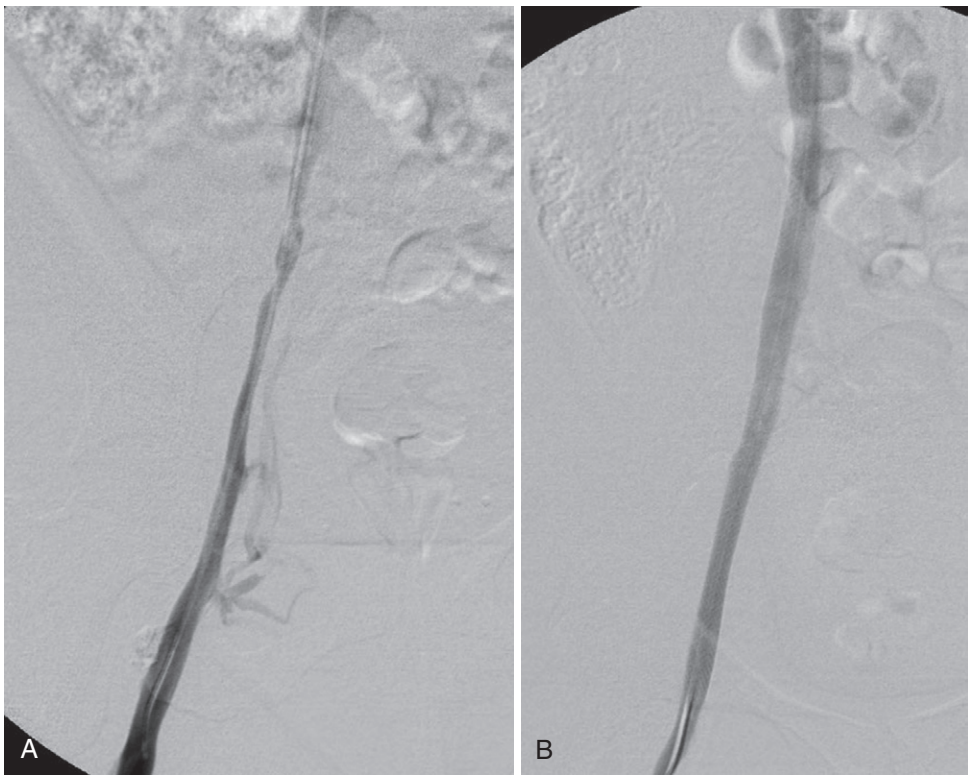

Figure 145-3 A 46-YEAR-OLD WOMAN WITH A PAST HISTORY OF RIGHT ILIOFEMORAL DVT 2 YEARS AGO NOW PRESENTS TO THE CLINIC COMPLAINING OF DAILY ACHING AND SWELLING IN THE RIGHT LOWER EXTREMITY THAT PRECLUDE AMBULATION FOR EVEN ONE BLOCK AND RENDER HER UNABLE TO WORK. These symptoms have been present since her previous DVT. **A,** A transjugular pelvic venogram demonstrates chronic narrowing of the right iliac vein with collateral formation. **B,** After placement of four 12-mm stents, the right iliac vein is widely patent. The pain and swelling improved, and the patient was subsequently able to return to work.

and dedicated wound care with topical antibiotics, exfoliants, and growth factors.[17] Despite these measures, PTS symptoms and venous ulcers often resist improvement and cause long-term hardships.

Because the severity of PTS symptoms often parallels the degree of ambulatory venous hypertension, endovascular interventions that eliminate venous obstruction and valvular reflux have been used for treatment of patients with severe PTS. Studies suggest that stent recanalization of chronically occluded iliac veins in patients with advanced PTS can be achieved in over 80% of patients and can reduce PTS symptoms, improve QOL, and enhance healing of venous ulcers[28] (Fig. 145-3). Accordingly, physicians who see patients with severe PTS, with or without ulcers, should consider consulting a venous endovascular specialist.

Inferior Vena Cava Filters

IVC filters are indicated for patients with proximal DVT or PE who have contraindications to or complications of anticoagulation, who develop symptomatic PE despite therapeutic-level anticoagulation, and/or who have severe cardiorespiratory compromise. In other circumstances, caution should be used when placing IVC filters because of ongoing uncertainty about their long-term risk-benefit ratio.[17] In the only available recent clinical trial, which was done in patients concomitantly receiving anticoagulant therapy and which was underpowered to detect an effect on fatal PE, filters appeared to provide additional protection against symptomatic PE but did not alter mortality.[29] Symptomatic recurrent DVT was increased in the filter group, but the overall rates of PTS and symptomatic recurrent VTE did not differ significantly. Because fatal PE rarely occurs in DVT patients who are properly anticoagulated, IVC filters should not be routinely placed in DVT patients. Patients who experience clinical failure of a first-line anticoagulant (e.g., warfarin therapy) can usually be switched to an effective alternative regimen, such as LMWH or a direct thrombin inhibitor.[30]

Retrievable IVC filters have the intended advantages of allowing PE prophylaxis during the period of highest risk, with subsequent removal thereafter. However, it should be noted that the stability and mechanical integrity of retrievable devices do not yet match those of older filters designed for permanent implantation and that many cases of retrievable filter migration have been reported.[27] Therefore if there is a strong likelihood that permanent IVC filtration will be needed, it is best to select a permanent nonretrievable IVC filter device. In DVT patients with a time-limited indication for an IVC filter, placement of a retrievable IVC filter is reasonable. However, it is important that the need for the IVC filter be reassessed every few weeks after placement so that the filter can be removed when it is no longer needed. Although many filters are placed with the intent to be retrieved, less than 50% are removed. Consequently, physicians must monitor patients with these devices to ensure that they are removed when appropriate.

At the health care system level, better studies of the use of IVC filters in different clinical scenarios should be considered an urgent priority because these devices are being used more frequently. The balance between PE prophylaxis and the long-term risks of IVC filter placement is complex and deserves more rigorous evaluation (Fig. 145-4).

FUTURE DIRECTIONS

Imaging-guided endovascular interventions have evolved significantly over the last 25 years and now offer the potential for improved patient outcomes in several disease states. For PAO, randomized trials have

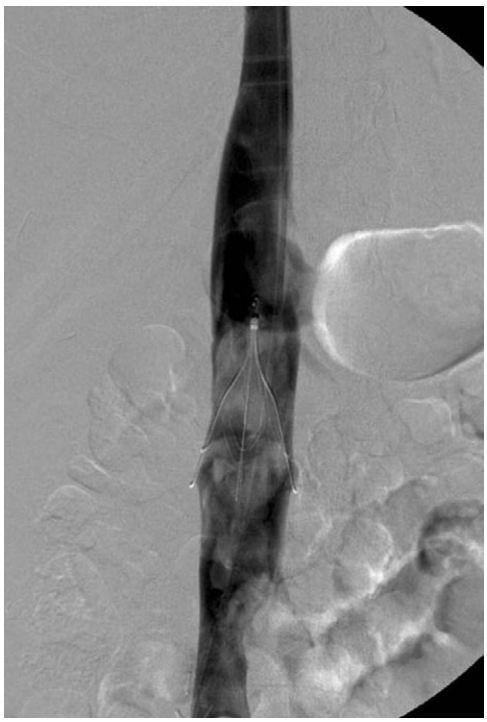

Figure 145-4 ILLUSTRATING THE COMPLEXITIES OF DETERMINING WHETHER IVC FILTERS ARE OF BENEFIT, A DIGITAL SUBTRACTION VENOGRAM SHOWS A LARGE GLOBULAR FILLING DEFECT WITHIN AN IVC FILTER THAT WAS PLACED 3 DAYS AGO. Filter proponents might argue that this represents a large, potentially fatal PE trapped within the filter, whereas filter opponents might propose that this is a case of filter-induced IVC thrombosis, a major complication. Who would be right?

defined the role for CDT for the treatment of acute limb ischemia. For DVT, a robust body of preliminary research supports the potential for catheter-based thromboreductive therapies to improve long-term patient outcomes, but randomized trials have not yet been completed to establish this benefit. Therefore an individualized approach is recommended to ensure that harms are minimized and appropriate patients are selected for intervention. Multidisciplinary collaboration between internists and endovascular physicians is needed to ensure optimal patient care.

CHAPTER 146

ATHEROTHROMBOSIS

Roy L. Silverstein

Morbidity and mortality from atherosclerosis, the pathologic process underlying acute myocardial infarction, sudden death, stroke, and limb loss, represent an enormous burden on society and health care systems. Even though death rates from heart attack and stroke have dropped precipitously over the past 60 years (69% and 76%, respectively, from 1950 to 2006), cardiovascular diseases are still the number one cause of death in the United States, accounting for more than 25% of all deaths—approximately 2300 per day.[1] Unfortunately, as the developing world adopts a more "Western" lifestyle (i.e., one marked by a high-fat, calorie-rich diet and limited physical activity), these statistics are becoming the norm worldwide. The annual financial burden of cardiovascular disease in the United States in 2010 was estimated by the American Heart Association (AHA) to be $445 billion, including $172 billion due to lost productivity.[2] These costs are predicted to triple over the ensuing 20 years; analyses of population survey data predict an increase in cardiovascular disease prevalence from 36.9% to 40.5%. It is interesting to note that as treatment of the acute complications of atherosclerosis improves, the burden of chronic complications, particularly heart failure, is expected to increase by as much as 25% over the next 20 years.[3]

Much of our knowledge of the epidemiology of cardiovascular disease comes from large-scale, long-term population studies, the most important being the Framingham Heart Study sponsored by the National Heart, Lung, and Blood Institute (NHLBI).[4] This ongoing prospective study began in 1948 with a cohort of ≈5200 men and women between the ages of 30 and 62 in Framingham, Massachusetts, and has since added two subsequent generations and several other cohorts. Through this study and others it elsewhere in the United States and in Europe, major risk factors for cardiovascular disease have been identified, including cigarette smoking, low-density lipoprotein (LDL) cholesterol, systolic blood pressure, male sex, menopause, physical inactivity, body mass index, and high-sensitivity C-reactive protein (hsCRP). Additionally, high-density lipoprotein (HDL) was identified as a protective factor. Based on these data, risk scores have been developed to guide physicians and patients, and public health campaigns developed targeting hypertension, elevated cholesterol, and lifestyle modifications. These have clearly contributed to the reductions in cardiovascular mortality just noted.

PATHOBIOLOGY

Atherosclerosis is caused by the progressive formation of arterial plaques, which are characterized by accumulation of lipids, in particular cholesterol and its derivatives, and inflammatory cells in the tunica intima of large- and medium-sized arteries (Fig. 146-1). Although occlusion of blood flow by plaque encroachment into the lumen can occur and cause ischemia of downstream tissues, most of the severe clinical events associated with atherosclerosis derive from acute or subacute thrombosis at a site of an unstable, inflamed, or ruptured plaque or at a site of recent mechanical or pharmacologic intervention. The past 40 years have seen a remarkable increase in our understanding of the basic pathophysiologic mechanisms that govern plaque formation, plaque progression and acute arterial thrombosis.[5,6] Translation of this knowledge into diagnostic, preventive, and therapeutic strategies has been impressive, but there is still much unmet need for improvement. This chapter will summarize the current prevailing models of atherogenesis and atherothrombosis, highlighting some key knowledge gaps and potential new therapeutic targets.

LIPOPROTEIN HOMEOSTASIS AND THE "CHOLESTEROL HYPOTHESIS"

Human epidemiologic and clinical trial data and animal model studies show unequivocally that elevated levels of plasma lipids, especially LDL cholesterol, are essential for plaque development. Atherosclerotic lesions can be induced in "atheroresistant" animals, including mice and rabbits, by manipulating their diets and/or genomes to cause hypercholesterolemia.[7] In humans, raising LDL cholesterol levels increases the risk for atherosclerosis proportionally and lowering levels either by lifestyle change or pharmacologic intervention reduces risk proportionally. In general, lowering LDL cholesterol levels by 10% reduces risk for cardiovascular events by 25% and cardiovascular death by 10%.

Normally, cholesterol levels are tightly controlled in response to diet and cellular needs by a complex transcriptional pathway mediated by sterol response element–binding protein 2 (SREBP2).[8] At low levels of cellular cholesterol, SREBP2 is activated and binds to specific DNA sequences in target genes known as *sterol response elements* to activate their transcription. Two key target genes are HMGCR and LDLR, which encode 3-hydroxy-3-methylglutaryl coenzyme A (HMGCoA) reductase (the rate-limiting enzyme in cholesterol biosynthesis) and the LDL receptor, respectively, thereby increasing both cholesterol production and cellular LDL uptake. At high levels of cellular cholesterol, SREBP2 is inactive, cholesterol biosynthesis is turned off, and LDL receptor expression is downregulated. As shown in Fig. 146-2, statin drugs decrease cellular cholesterol biosynthesis by inhibiting HMGCoA reductase and thereby induce an increase in LDL receptor expression, driving down plasma LDL cholesterol levels.

Multiple randomized clinical trials have demonstrated efficacy of statin class drugs in reducing risk for cardiovascular events in high-risk individuals. Initial studies focused on secondary prevention in patients with a history of a previous atherosclerotic event, but more recent trials have demonstrated efficacy as part of a primary prevention strategy in subjects with elevated LDL cholesterol or in subjects with normal LDL cholesterol in the setting of other risk factors, such as diabetes, hypertension, or elevated plasma levels of hsCRP.[9] The latter studies, along with those showing benefit of lowering LDL cholesterol to levels well below "normal" (e.g. to 70 mg/dL in high-risk individuals),[10] are consistent with the concept that "normal" levels of LDL cholesterol, as defined by population means in the Western world, are not reflective of a true normal biology.

Recent genetic studies of rare individuals with extremely low LDL cholesterol levels identified a null mutation in a gene known as *PCSK9* that encodes an enzyme involved in downregulating LDL receptor expression.[11] These individuals seem to be otherwise normal, despite nearly absent LDL, suggesting that targeting this enzyme

could represent a new strategy for cholesterol-lowering therapeutics. Phase I and II trials of PCSK9 inhibitors are, in fact, already underway.

Cells in the periphery have the capacity to eliminate excess cholesterol through a process known as *reverse cholesterol transport (RCT).*[12] In this pathway, summarized in Fig. 146-3, postlysosomal trafficking of intracellular cholesterol to the plasma membrane, mediated in part by actions of acyl-CoA cholesterol acyltransferase (ACAT) and Neimann-Pick type C (NPC) protein, allows the cell surface adenosine triphosphate (ATP)–binding cassette (ABC) proteins ABCA1 and ABCG1 to transport excess cholesterol to apolipoprotein A (apoA) containing lipoproteins, either nascent HDL (in the case of ABCA1) or mature HDL (in the case of ABCG1). HDL then "delivers" the cholesterol back to the liver, where it is selectively taken up by hepatocytes through a protein known as *scavenger receptor B1 (SRB1)* and ultimately secreted into bile and excreted in feces. The role of HDL in RCT probably accounts for its association with lowered risk for cardiovascular disease, but HDL particles also contain antiinflammatory and antioxidant proteins that may also contribute to lowering atherosclerosis risk.

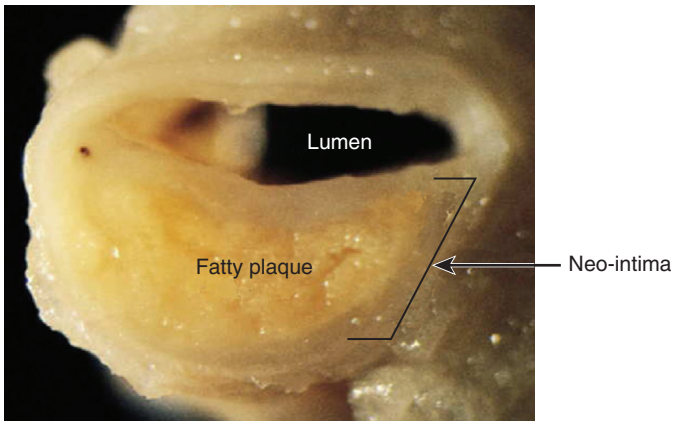

Figure 146-1 ATHEROMATOUS PLAQUE. Cross-sectional view of a human artery taken from an autopsy, showing accumulation of yellow-colored fatty materials in neointima.

Pharmacologic and lifestyle approaches to enhance RCT have received significant attention as potential antiatherosclerosis strategies. HDL levels can be raised by physical exercise, as well as by moderate alcohol ingestion. The only FDA-approved pharmacologic agent capable of raising HDL is niacin, but high doses are required and these are not easily tolerated because of side effects, especially facial flushing. A combination of high-dose niacin with a prostaglandin D_2 receptor antagonist to block facial flushing is currently under study.

The circulating plasma enzyme, cholesterol ester transfer protein (CETP), functions to transfer cholesterol esters from HDL to VLDL (very low-density lipoprotein) and LDL (Fig. 146-3). Inhibiting this enzyme raises HDL levels (and lowers LDL) significantly in humans, but a large phase III randomized clinical trial with the initially developed pharmacologic CETP inhibitor torcetrapib was halted in 2006

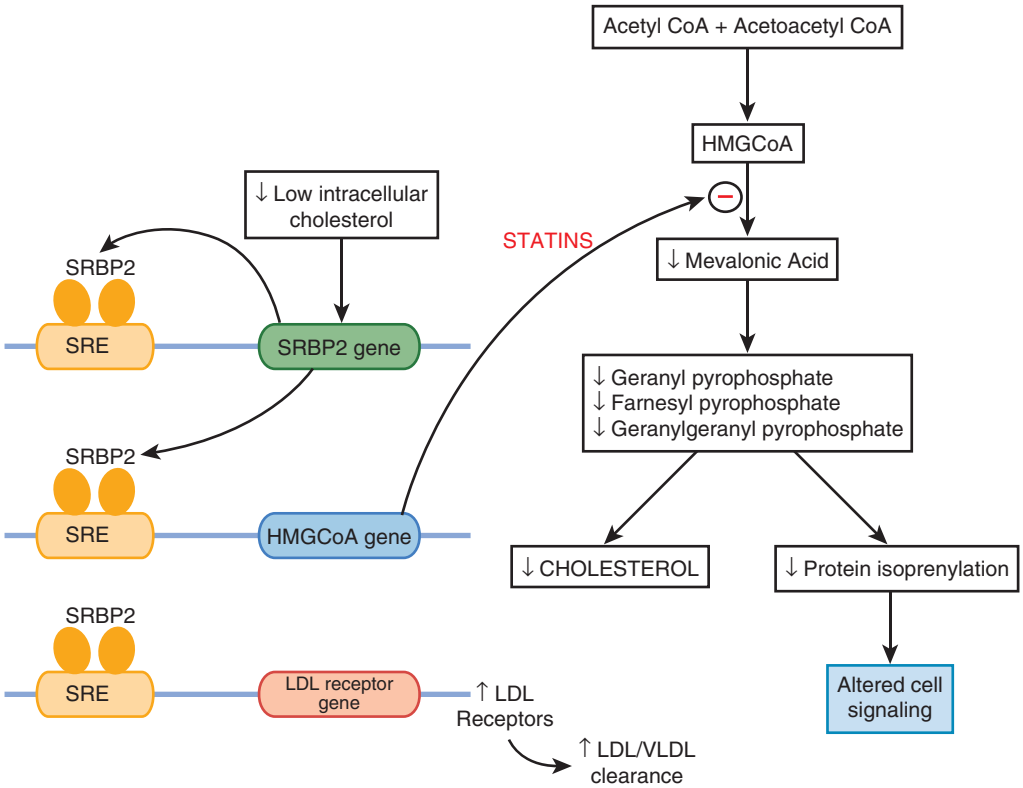

Figure 146-2 STATINS TARGET CHOLESTEROL AND ISOPRENYLATION PATHWAYS. The statin class of drugs inhibits the intracellular enzyme 3-hydroxy-3-methylglutaryl coenzyme A (HMGCoA) reductase. This enzyme converts HMGCoA to mevalonic acid, which is a precursor in the biosynthesis of the isoprenoids geranyl and farnesyl pyrophosphates, which in turn are precursors of cholesterol, as well as intermediates in isoprenyl modification of proteins, including small-molecular-weight G proteins. Since HMGCoA reductase is the rate-limiting step in these pathways, its inhibition leads to decreases in cholesterol biosynthesis, hepatic VLDL production, and protein isoprenylation *(arrows).* Low levels of intracellular cholesterol activate the SRBP2 gene *(green),* which encodes a transcription factor that binds to sterol response elements (SRE) in multiple genes, including HMGCoAR and LDL receptor. The ensuing increased expression of LDL receptor results in increased clearance of apoB-containing lipoproteins (LDL and VLDL) from plasma, further lowering plasma cholesterol levels.

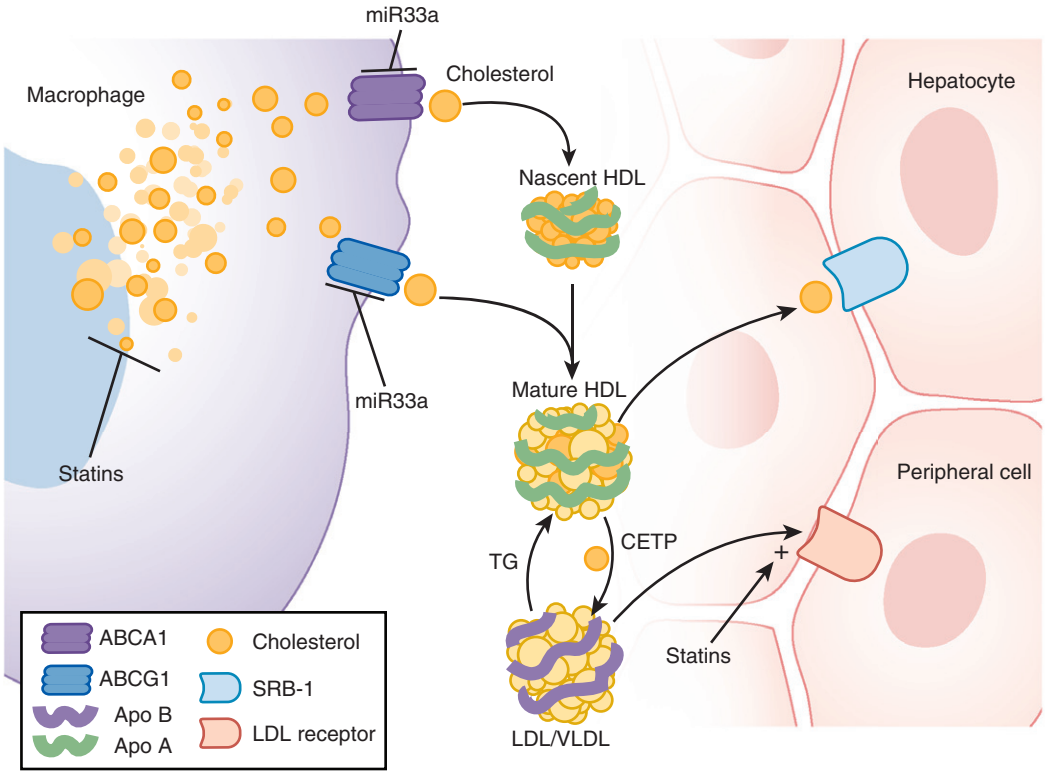

Figure 146-3 REVERSE CHOLESTEROL TRANSPORT. Cells in the periphery, including macrophage foam cells, have the capacity to unload intracellular cholesterol via two members of the ATP-binding cassette (ABC) transporter family: ABCA1 and G1. The former transfers cholesterol to apoA and/or nascent HDL particles, whereas the latter transfers cholesterol to mature HDL. HDL interacts with scavenger receptor B1 (SRB1) on liver cells, and through a process known as *selective cholesterol uptake,* the cholesterol within the HDL is internalized, where it can ultimately be reused or excreted via bile. The cholesterol in HDL can exchange with triglycerides (TG) in LDL and VLDL particles through the action of an enzyme, cholesterol ester transfer protein (CETP). Inhibitors of CETP thus raise plasma HDL levels and lower LDL levels. LDL and VLDL are normally cleared by cells in the periphery via internalization by LDL receptor. Statin drugs, by inhibiting HMGCoA reductase, lower intracellular cholesterol levels and raise LDL levels, thus lowering plasma LDL. A microRNA miR33a encoded within the SREBP gene blocks expression of ABCA1 and ABCG1.

because of excessive all-cause mortality in the treatment group receiving a combination of atorvastatin and the study drug.[13] This result may have been due to an off-target effect of the drug, but nevertheless, development of this strategy has been significantly slowed. Several other CETP inhibitors are, however, under development and in phase II studies showed efficacy in raising HDL and lowering LDL. Of interest, a microRNA, miR-33a, encoded by a DNA sequence embedded in the SREBP2 gene was found to repress several key genes involved in cholesterol homeostasis (see Fig. 146-3), including ABCA1 and ABCG1, as well as genes involved in fatty acid oxidation and glucose metabolism.[14] Blocking miR-33a in mice increased HDL levels and inhibited atherosclerosis, suggesting that this could be a good target for therapeutic development. Other strategies under development to enhance RCT include direct infusion of cholesterol acceptors from ABCA1 or G1, including recombinant apoA, or a "hyperfunctioning" apoA mutant known as *apoA Milano,* or a small apoA mimetic amphipathic peptide.

FOAM CELL FORMATION AND THE FATTY STREAK

Atherosclerotic plaque develops in a geographically discontinuous manner very slowly and is continuously evolving over many decades.[5,6] Autopsy studies of motor vehicle accident victims showed early "preatherosclerotic" lesions present in the aorta of otherwise healthy young children. These small superficial lesions consist predominantly of lipid-laden macrophages and are termed *fatty streaks.*

The initial event in atherogenesis is most likely transudation of apolipoprotein B–containing lipoproteins across the endothelial cell monolayer into the arterial wall (Fig. 146-4). These lipoproteins are predominantly LDL, which is derived by remodeling of VLDL particles secreted into the plasma by hepatocytes. So-called remnant lipoproteins derived from chylomicrons produced by the intestinal epithelium may also play a role. The primary sites of lipoprotein entry are at arterial branch points or curvatures, explaining the discontinuous nature of atherosclerotic lesions. These locations are where normal laminar blood flow is disturbed. Normal laminar flow activates a specific genetic "protection" program in endothelial cells that enhances barrier function and promotes an antiinflammatory, antioxidant, antiatherogenic phenotype.[15] Loss of these shear-dependent signals disrupts the normal endothelial architecture and increases permeability, allowing unregulated entry of lipoproteins into the tunica intima. Within the intima the lipoproteins become "trapped" by specific interactions with normal components of the vessel wall, such as glycosoaminoglycans, and undergo structural modifications, including aggregation, oxidation, and in settings of hyperglycemia, glycation.[16]

Just as data show an unequivocal role for LDL cholesterol in atherogenesis, equally compelling studies in humans and animal models show that mononuclear phagocytes are necessary for plaque formation and progression and that atherosclerosis is associated with a chronic inflammatory state in the vessel wall and in the systemic circulation.[17,18] Targeted genetic mutations that block monocyte development from hematopoietic precursors or that prevent

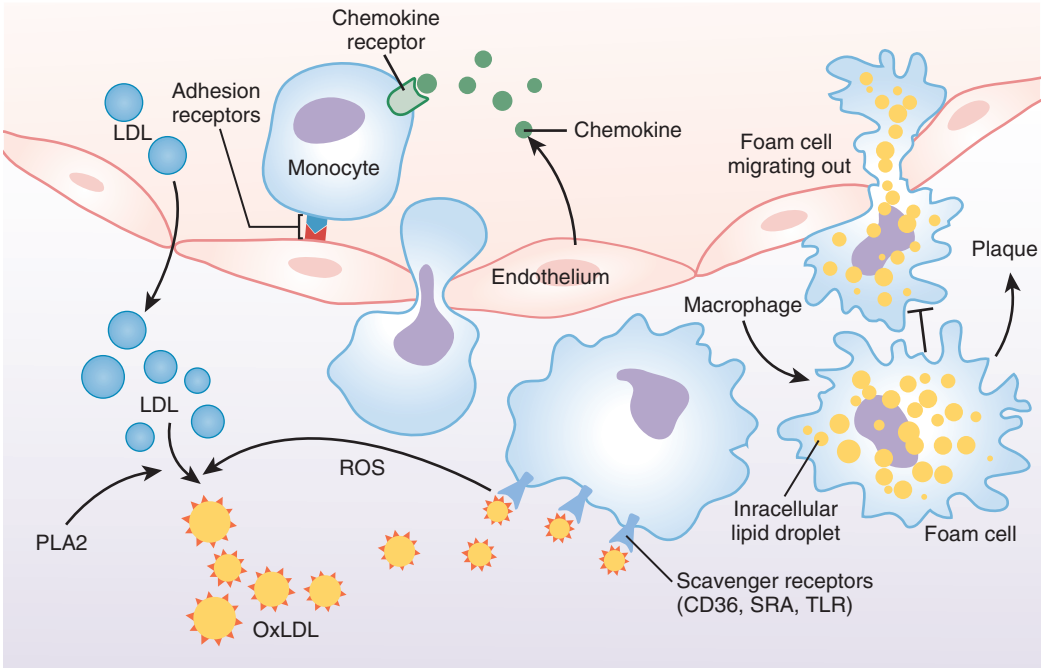

Figure 146-4 FOAM CELL FORMATION IS AN EARLY EVENT IN ATHEROGENESIS. LDL particles, which are transudated through a dysfunctional endothelium at arterial branch points or areas of disrupted shear, enter the intima and become trapped within the extracellular matrix. In the presence of inflammation, the LDL particles become oxidized or otherwise modified and contribute to endothelial dysfunction by interacting with receptors on endothelial cells, such as LOX1. Monocytes, in response to chemokines secreted by activated endothelial cells and/or inflammatory leukocytes and platelets, adhere to the endothelium via selectin family adhesion receptors, as well as β2 integrins and their counter receptors (ICAM and VCAM). The monocytes then diapedese into the intima, where they differentiate into inflammatory macrophages that generate oxidant stress within the vessel wall and release proinflammatory mediators. Scavenger receptors, in particular CD36, expressed on macrophages recognize and internalize oxidized LDL, leading to a feed-forward loop of increased LDL oxidation and increased scavenger receptor expression, resulting ultimately in the formation of cholesterol-laden foam cells. These accumulate in the intima, in part because of signals induced by oxLDL that inhibit migration, forming plaque.

monocyte trafficking into tissues dramatically protect mice from experimental atherosclerosis. The earliest and most prominent cell type in human and mouse atherosclerotic lesions are monocytes and macrophages. Initial monocyte entry into the arterial intima is in response to poorly understood cues related to endothelial cell dysfunction. Environmental and genetic influences, such as hypertension, angiotensin II production, cigarette smoke, diabetes, metabolic syndrome, and chronic periodontal infection may contribute to generalized endothelial dysfunction, but it is likely that the modified lipoproteins, particularly oxidized LDL (oxLDL), trapped in the vessel wall play a major initiating role. The oxLDL can activate an endothelial cell receptor known as *LOX1* to induce expression of monocyte adhesion molecules and this response is dramatically amplified in the presence of angiotensin II.[19] Other components of the "dysfunctional" endothelial cell phenotype include von Willebrand factor release from Weibel-Palade bodies and altered homeostasis of nitric oxide and eicosanoid pathways.

Monocyte recruitment to the vessel wall (see Fig. 146-4) begins with their capture and rolling along the activated endothelium mediated by specific interaction of selectin family adhesion molecules (L-selectin on circulating monocytes and P-selectin on activated endothelial cells) with their counter receptors, including PSGL1. Subsequent signals induced by endothelial-derived chemokines, including CCL5/RANTES, CCL2/MCP1, IL-8, and CXCL1, lead to further recruitment of monocytes and facilitate firm adhesion of the rolling monocytes to the vessel wall.[18,20] The latter is mediated by interaction of ICAM1 and VCAM on the activated endothelial surface with specific integrin family counter receptors on monocytes, β2 integrins for ICAM1 and α4β1 for VCAM. The adherent monocytes then diapedese through disrupted endothelial junctions and enter the intima. Recent studies have suggested that a particular subset of circulating "inflammatory" monocytes, defined by high expression of the Ly6C antigen (in mice) or CD14 (in humans), are the predominant source of entering cells.[18] The normal vasculature also contains a small number of resident macrophages, as well as "patrolling" monocytes. The latter are distinct from the $Ly6C^{+}$/$CD14^{hi}$ cells and exhibit a less inflammatory phenotype.

The ultimate fate of monocytes within the intima is probably determined in part by lineage commitment programs carried by the entering monocytes and in part by local environmental cues. Most, however, seem to polarize toward the so-called M1 inflammatory macrophage phenotype. Investigators have, however, detected dendritic cell-like phenotypes (expressing CD11c), as well as M2-like (expressing arginase and eNOS) and proangiogenic (expressing VEGF) macrophage phenotypes within plaque. In addition to monocytes, small numbers of lymphocytes, particularly T cells, also enter the intima, where they contribute to plaque formation by secreting cytokines and other mediators.

Reactive oxygen species (ROS) generated by the inflammatory milieu within the atherogenic vessel wall modify the trapped LDL by oxidizing both protein and lipid moieties (see Fig. 146-4), creating what are called collectively *oxLDL.*[16] Modified LDL lose their affinity for the LDL receptor but gain affinity for a genetically unrelated family of receptors known as *scavenger receptors (SR),* including SRA1 and CD36, which are present at high levels on the macrophage surface. These receptors are part of the innate immune system, and their recognition of specific structures within oxLDL presumably relates to their mimicry of similar structures found on pathogenic organisms. CD36, for example,[21] also recognizes mycobacterial and *Staphylococcus* cell wall components, certain fungal structures, and

falciparum malaria–infected erythrocytes. TLR family members, including TLR2, TLR4, and TLR6, can also recognize modified LDL and can partner with CD36 in these functions. Unlike the LDL receptor, which is downregulated in the setting of excess ligand, SR expression is increased in the presence of oxLDL, in part via internalization of oxidized fatty acids that serve as ligands for PPAR family transcription factors, particularly PPARγ, which is a major positive regulator of CD36 expression.[22] Thus over many months and years, the continued entry and oxidation of LDL in the intima coupled with upregulated expression of SRs leads to massive intracellular accumulation of cholesterol and formation of lipid-laden cells known as *foam cells*.

OxLDL-SR interactions initiate a cascade of events in macrophages, including internalization of the bound oxLDL, activation of proinflammatory pathways, and activation of transcriptional pathways. The CD36-oxLDL interaction, in addition to promoting ROS formation, also decreases expression of endogenous antioxidant pathways and inhibits macrophage migration.[21] These events result in a feed forward loop that increases leukocyte recruitment into the vessel wall, inhibits macrophage migration out of the vessel wall, and increases oxLDL formation. The net effect is formation and accumulation of lipid-laden foam cells and proinflammatory immune cells, which together form plaque (see Fig. 146-4). In mouse models, genetic deletion of scavenger receptors, especially CD36, provides substantial protection from plaque formation.

Although abundant data from animal models and correlative human studies support the oxidative stress hypothesis, considerable controversy remains because large- and medium-sized interventional trials of antioxidant therapy in humans have generally failed to prevent the complications of atherosclerosis.[19] These trials, however, are difficult to interpret because of lack of convincing evidence that the tested "antioxidant" therapies actually targeted the relevant vascular or circulating oxidant pathways. These oxidant systems include NADPH oxidase, xanthine oxidase, myeloperoxidase (MPO), and uncoupled nitric oxide synthase. MPO is of particular interest because it generates a highly specific oxidized phospholipid ligand for CD36 from LDL and because circulating MPO levels associate with risk for atherosclerosis and with risk for acute cardiovascular events.

Another potential problem with the antioxidant clinical trials is that the choice of antioxidants may have been flawed. Most used vitamin E formulations containing mainly α-tocopherol. Recent studies showed that tocopherols, in addition to having activity as antioxidants, have important cell-signaling functions mediated by specific cellular receptors. Therapy with formulations containing primarily α-tocopherol may downregulate endogenous γ-tocopherol levels, leading to imbalance in natural tocopherol signaling pathways. Furthermore, tocopherols are lipid-based structures that are themselves subject to oxidation, producing lipid peroxides that can actually promote further oxidative stress. Nevertheless, it is possible that pathways of cholesterol uptake unrelated to LDL oxidation and SR expression, such as by micro- and macro-pinocytosis of "native" LDL or aggregated LDL, may play a significant role in foam cell formation.

Important unresolved issues in the pathogenesis of early atherosclerotic lesions include understanding why macrophages do not exit the vessel wall and travel to regional nodes after ingesting modified LDL, as they would after ingesting exogenous pathogens, and why cholesterol efflux cannot keep up with LDL uptake to maintain a homeostatic state.[23] OxLDL inhibition of macrophage migration (see Fig. 146-4) may explain the former, suggesting that blocking oxLDL-mediated signaling pathways might have therapeutic potential by facilitating macrophage exit from developing plaque. In experimental animals, transplantation of atherosclerotic aortae from hypercholesterolemic animals into normal recipients induces migration of lipid-laden macrophages out of the vessel wall and plaque regression.[24] The second issue might relate to differential gene regulation of SRs compared with cholesterol efflux transporters, and/or to intracellular cholesterol trafficking that might make it inaccessible to efflux transporters. In addition, HDL particles, similar to LDL, are sensitive to oxidative modification and such oxidation may produce what is termed "dysfunctional" HDL—that is, HDL particles that do not function optimally in RCT and that may lose some of their other atheroprotective activity.[25]

LESION EVOLUTION: REMODELING AND THE VULNERABLE PLAQUE

In humans, plaque develops and evolves very slowly over many decades, explaining in part why animal models in which advanced lesions develop rapidly over weeks and months may not accurately reflect the human condition. Accumulation of foam cells is only one component of the atherogenic process. Early on, signals from macrophages (Fig. 146-5) and the injured endothelium, primarily platelet-derived growth factor (PDGF), stimulate adventitial smooth muscle cells to migrate into the intima and proliferate.[6] These cells contribute to the mass of the lesions and also secrete collagen and other factors that change the nature of the intimal extracellular matrix. Lymphocytes infiltrating from the circulation and mast cells from the adventitia also contribute to the inflammatory milieu and matrix remodeling. Platelet antigens are also readily detectable in plaque,[26] suggesting that platelets enter the intima, where they may contribute to matrix remodeling and the inflammatory state by secreting PDGF, transforming growth factor-β, and other growth factors, along with platelet factor 4, which is a potent chemokine, also known as *CXCL4,* for monocytes. Animal studies suggest that platelets may facilitate monocyte recruitment, acting as a bridge between the endothelium and circulating monocytes (see Fig. 146-5). Sophisticated single-cell imaging studies in mice showed that monocytes continue to traffic through the "shoulders" of even advanced stage lesions.

Plaque generally grows in an eccentric pattern within the intima and in certain instances can create significant obstruction to blood flow (Fig. 146-6, *left*). In such cases, as oxygen demand increases, tissue ischemia results, leading to angina and/or lower extremity claudication. Recent in vivo studies using sophisticated imaging techniques, such as intravascular ultrasound, however, demonstrate that in most cases, the vessel wall remodels as plaque grows (Fig. 146-6, *right*) so that the arterial lumen is mostly preserved and the bulk of the atheromatous mass is ablumenal.[10,27] These studies show that traditional two-dimensional angiographic techniques vastly underestimate plaque burden. Of note, such studies along with careful histopathologic examinations, have led to the concept that the "quality" of the plaque may be more important than its quantity in predicting cardiovascular outcomes. Some plaques, particularly those with thick fibrous caps and cellular cores seem to be "stable" (Fig. 146-7), whereas others, particularly those with thin fibrous caps, abundant leukocytes, and necrotic, lipid-rich cores seem to be "unstable" and vulnerable to erosion and rupture (see Fig. 146-7). Rupture refers to the sudden loss of integrity of the fibrous cap with release of plaque material into the lumen, often followed by acute occlusive thrombosis. Erosion is a more subtle concept referring to loss of endothelial cells at the shoulder of the lesion or minimal leakage of plaque through a partially disrupted cap. Plaque erosion may lead to subocclusive thrombus formation and/or intraplaque hemorrhage and thrombosis. Repeated cycles of erosion and intraplaque hemorrhage/thrombosis may account for the apparent stepwise growth of some lesions.

Understanding factors that contribute to plaque vulnerability is an extremely important topic of research, but one that is difficult to model in animals. Some key features that have emerged are the degree of angiogenesis within the plaque, the balance of matrix-degrading enzymes and enzyme inhibitors, the level of apoptosis of cells within the plaque, and the deposition of calcium within the plaque.

Plaque angiogenesis is a recently appreciated process that can be visualized by certain imaging modalities, such as ultrafast CT and MRI, in real time.[27] Based on analogy to tumor growth, it is not surprising that growing plaque requires a blood supply and also that the neovessels within plaque may, similar to their counterparts in cancer, be leaky and unstable. This neovascular instability may

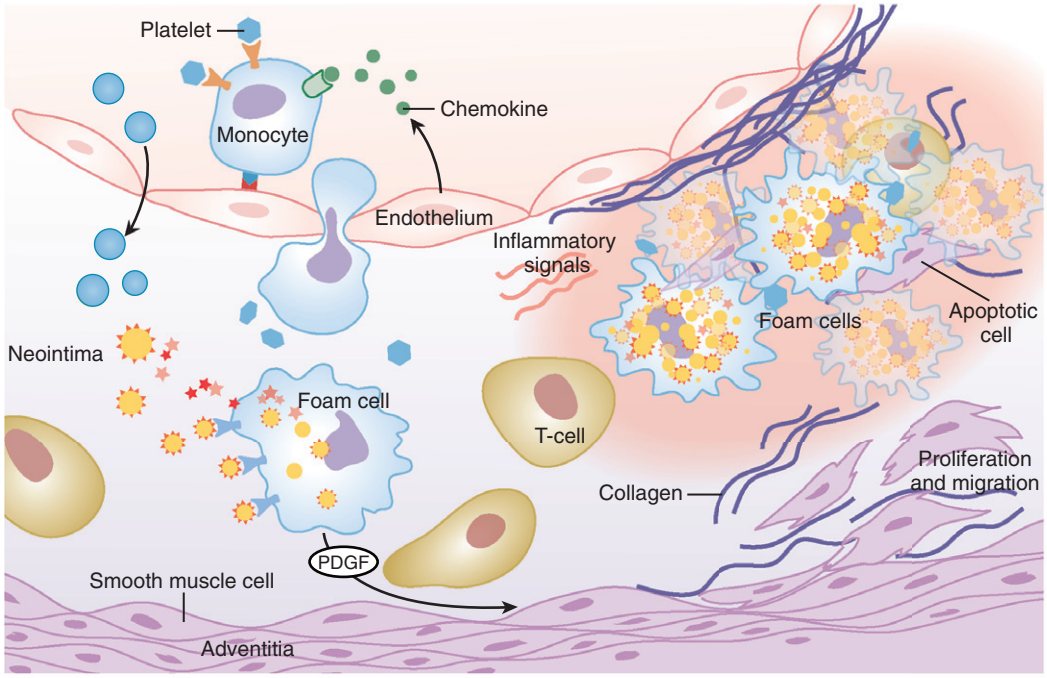

Figure 146-5 LATER EVENTS IN ATHEROGENESIS. Fatty streaks formed in the vessel wall via accumulation of foam cells (see Fig. 146-4) evolve over many years into complex plaque. In response to chemokines, monocytes continue to enter plaque, perhaps accompanied by platelets. T cells, B cells, and other inflammatory cells also accumulate. Cholesterol loading of macrophages induces apoptosis and apoptotic cells accumulate because of dysfunction of normal efferocytotic clearance pathways. Smooth muscle cells respond to PDGF, TGFβ, and other signals and proliferate and migrate into the neointima. These cells produce collagen and other matrix components, contributing to plaque growth and formation of a fibrous cap. To support plaque growth, an angiogenic response is elicited from vasa vasora within the adventitia.

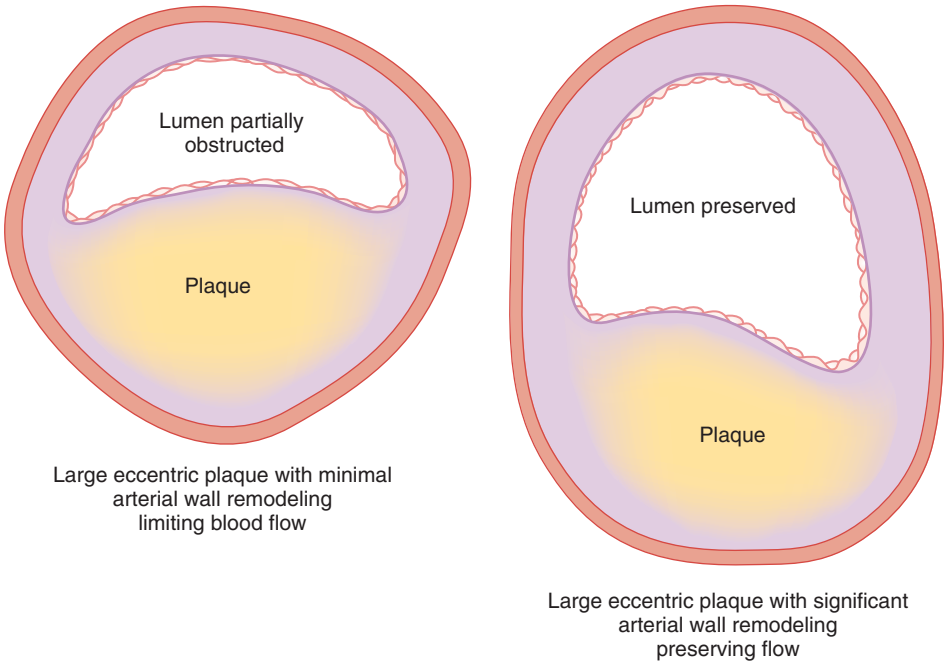

Figure 146-6 VESSEL WALL REMODELING CAN PRESERVE ARTERIAL LUMEN. On the left is a cross-section cartoon image of an artery containing a large eccentric plaque *(orange)*. The vessel has undergone minimal remodeling. The atheromatous lesion is extending into the arterial lumen and would be visible on an angiogram as an obstructing lesion. On the right is a lesion of similar mass, but its formation was accompanied by significant vessel wall remodeling so that the lesion extends mainly into the vessel wall, preserving the lumen. On an angiogram this would be nearly invisible.

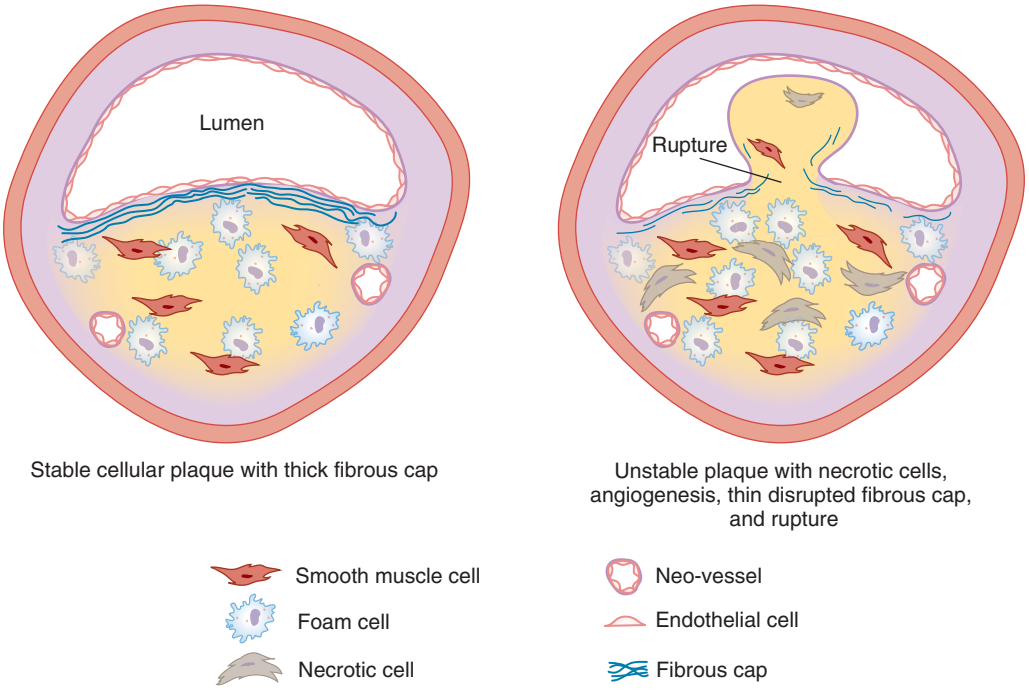

Figure 146-7 UNSTABLE PLAQUE IS PRONE TO RUPTURE. On the left is a cross-section cartoon image of an artery with a plaque containing abundant smooth muscle cells and foam cells and a thick fibrous cap. On the right is a similar-size plaque, but with a thin fibrous cap that has ruptured allowing plaque contents to extrude into the lumen. This plaque contains smooth muscle cells and foam cells, as in the stable plaque on the left, but there is abundant angiogenesis, along with apoptotic and necrotic cells.

contribute to plaque instability by facilitating entry of inflammatory cells, platelets, and plasma components, such as fibrinogen and cell-derived microparticles (MP). In animal models, treatment with anti-angiogenic agents significantly slows plaque growth. In some diseases states, such as diabetes, accelerated atherosclerosis may reflect a "microvascular" disease of the vasa vasorum.

Integrity of the fibrous cap is maintained by a balance between collagen synthesis by smooth muscle cells and fibroblasts and collagenolysis by matrix-degrading enzymes. The latter is maintained by a balance between enzymes and their endogenous inhibitors. The predominant enzymes are members of the large family of zinc-dependent matrix metalloproteinases (MMPs) that are capable of degrading most matrix components, including collagen. These enzymes are tightly regulated by a network of activators and inhibitors and in settings in which activation exceeds inhibition, excessive matrix degradation may occur. Metalloproteases of the ADAM (a disintegrin and metalloprotease domain) family and ADAMTS (a disintegrin and metalloprotease domain with thrombospondin structural homology domains) family may also contribute to plaque instability. Although several clinical trials have studied MMP inhibitors in atherosclerosis, none has shown clear benefit to date.

A prominent feature of advanced atherosclerotic lesions is the presence of apoptotic cells, mostly of macrophage and smooth muscle cell origin. The nature of the proapoptotic signals within plaque is incompletely understood, but excess intracellular cholesterol can initiate the endoplasmic reticulum stress response leading to apoptosis.[28] OxLDL signaling through SRs and/or TLRs can also induce apoptosis.[17] A recent study showed that lipoprotein(a), a known risk factor for cardiovascular disease can function as a "carrier" for oxLDL and thereby activate the CD36/TLR2 signaling complex to trigger apoptosis in the setting of ER stress. In most inflammatory sites, apoptotic leukocytes are quickly removed by phagocytes in a process known as *efferocytosis*. The efferocytotic macrophages are generally thought to be of the M2, antiinflammatory type; thus their engagement by apoptotic cells not only removes the apoptotic cell from the microenvironment, but also directly contributes to downregulation of the inflammatory state by inducing secretion of antiinflammatory cytokines and effectors. In atherosclerotic plaque, this process seems to be inefficient so that apoptotic cells accumulate, contributing to the lipid load and releasing potentially toxic contents.

Although therapeutic interventions to stabilize vulnerable plaque or prevent plaques from becoming vulnerable have not yet materialized, several imaging approaches have been studied in attempt to develop useful biomarkers to identify vulnerable plaque and therefore to identify patients who might benefit from aggressive antithrombotic and lipid-lowering therapeutic interventions. Neovascular imaging by CT or MRI are promising technologies, as are plaque characterization by optical coherence tomography, near infrared imaging, and thermography.[27]

PLAQUE RUPTURE AND ACUTE ARTERIAL THROMBOSIS

The devastating complications of atherosclerosis, including acute coronary syndromes (ACS), stroke, gangrene, and sudden death result primarily from acute and subacute thrombosis occurring at the site of plaque rupture (Fig. 146-8). As described in later chapters in this section, treatment and prevention strategies using aggressive antiplatelet, anticoagulant, fibrinolytic, and/or mechanical approaches have been remarkably effective at reducing major cardiovascular events, but tremendous unmet need still exists, particularly in the areas of primary and secondary prevention of thrombosis.

The pathophysiologic mechanisms underlying acute arterial thrombosis center on two key concepts: (1) exposure of prothrombotic materials to the local circulation as a consequence of plaque rupture acts as a thrombotic trigger, and (2) advanced atherosclerosis is associated with a systemic prothrombotic state that accelerates or enhances pathologic thrombosis.[29,30] The former mechanism undoubtedly plays a major role. Immunohistochemical studies have convincingly shown that plaque contains abundant tissue factor (TF), and acute anticoagulation therapy directed toward blocking thrombin generation or inhibiting thrombin has proven to be effective in ACS.

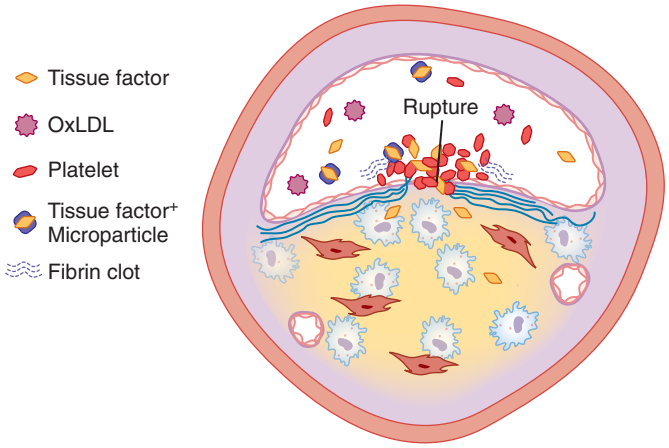

Figure 146-8 ACUTE PLATELET-RICH THROMBUS AT SITE OF PLAQUE RUPTURE. An atherosclerotic artery with a ruptured plaque (as described in Fig. 146-7) serves as a nidus for formation of an acute thrombus. Tissue factor (TF) contained in plaque or expressed on circulating microparticles (MPs) leads to thrombin generation and formation of fibrin at the site of rupture. Platelets accumulate at the rupture site and are activated by plaque components, such as collagen, forming an aggregate that, if large enough, can obstruct blood flow. Blood in patients with advanced atherosclerosis is prothrombotic, in part because of oxidized LDL–induced release of TF-positive MPs from monocytes. Oxidized LDL also interacts with platelets to make them more sensitive to activation and aggregation by plaque contents.

Plaque TF is derived mainly from smooth muscle cells, fibroblasts, and activated macrophages. Recent studies have also suggested that platelets can synthesize TF after stimulation by inflammatory mediators and thus may also contribute to the plaque procoagulant load. A significant proportion of plaque TF may be in the form of membrane-bound microparticles (MP) derived from apoptotic and/or activated cells (see next section for more detailed explanation). Exposure of flowing blood to TF exposed in or released from ruptured plaque leads to rapid activation of factor Xa, thrombin generation, and activation of platelets. In addition to TF, other components of plaque that become exposed to blood at sites of rupture include collagen and oxidized phospholipids, both of which can activate platelets directly. Thus aggressive antiplatelet therapy with aspirin, ADP receptor P2Y12 inhibitors, and glycoprotein αIIbβ3 inhibitors are mainstays of the pharmacologic approach to treatment of ACS, and aspirin and P2Y12 inhibitors are of proven efficacy for secondary prevention.

HYPERLIPIDEMIA, ATHEROSCLEROSIS, AND A SYSTEMIC PROTHROMBOTIC STATE

Platelet hyperreactivity has long been thought to play a role in acute atherothrombosis. Clinical studies support an association between in vitro platelet reactivity and prognosis in patients with coronary disease, and it was shown in the 1970s that platelets from patients with familial hypercholesterolemia were more sensitive to activation by epinephrine or ADP. Similar findings were seen in platelets from mouse models of hyperlipidemia, such as the apoE-null strain, which was fed a high-fat diet. Of note, the time to form occlusive thrombi after arterial injury in vivo was accelerated in hyperlipidemic mice compared with controls. In that context, much attention has been paid to identifying and characterizing receptors on the platelet surface that recognize specific classes of lipids and lipoproteins.[31] The receptors fall into two main groups: pattern recognition innate immune receptors, including CD36, SRA, TLR4, and LDL receptor–like protein (LRP)-8 (also known as *apoER2*), and G-protein coupled receptors, including receptors for lysophosphatidic acid (LPA), platelet-activating factor, and thromboxane.

CD36 (also known as *platelet glycoprotein IV* or *IIIb*) is of particular interest because of its known function on macrophages as a high affinity signaling receptor for oxLDL and because oxLDL and oxidized phospholipids are readily detectable in circulating plasma of experimental animals and patients with atherosclerosis and hyperlipidemia. Indeed, recent studies showed that oxLDL bound to CD36 on the surface of platelets in a specific, concentration, and time-dependent manner. At high concentrations, such as might occur during acute plaque rupture, oxLDL activates platelets and at lower concentrations, such as those observed in the circulation of individuals with atherosclerosis, oxLDL-augmented platelet aggregation responses to low doses of "classic" platelet agonists, such as ADP and collagen. More recently, platelet CD36 was shown to bind MP and advanced glycated proteins, suggesting that circulating endogenous "danger signals" generated by oxidant stress, hyperglycemia, and inflammation could induce a prothrombotic state through this pathway.

Platelets also express SRB1, a CD36 family protein that functions in the liver as a cholesterol acceptor for HDL. The function of SRB1 on platelets is not well understood, but at least one study showed that oxHDL, but not native HDL, inhibited platelet reactivity to multiple agonists, including ADP, collagen, and thrombin via binding to SRB1. HDL is at least as susceptible to oxidation in vitro and in vivo as LDL, and it is possible that the balance between oxLDL and oxHDL and the relative expression levels of CD36, SRB1, and other receptors may determine platelet reactivity in patients with hyperlipidemia and oxidant stress.

Atherosclerotic plaque and so-called "minimally" oxidized LDL contain LPA, a biologically active lipid generated by the action of phospholipases on LDL and cell membrane lipids. Platelets express at least three different G-protein-coupled LPA receptors but the in vivo relevance of this system has not been demonstrated. Ex vivo studies, however, demonstrated that minimally oxidized LDL at high concentrations could induce platelet shape change and sensitize platelets to aggregate in response to other agonists. Epidemiologic studies have also associated levels of soluble phospholipase A2 with cardiovascular risk.[32] In addition to participating in LPA biosynthesis, this family of enzymes generates free fatty acids from phospholipids that serve as substrates for cyclooxygenase and lipoxygenases, producing both pro- and antiatherogenic eicosanoids.

LRP-8 (particularly a splice variant known as apoER2) binds lipidated apoE3 (e.g., chylomicrons and remnant particles) resulting in enhanced nitric oxide production and inhibition of platelet activation by ADP and other agonists. On the other hand, LRP-8 has also been shown to bind apoB-containing lipoproteins, leading to enhanced thromboxane generation and sensitization of platelets to other agonists. Consistent with this, in mice genetic deletion of LRP-8 has an antithrombotic effect in models of arterial injury.

In addition to platelet hyperreactivity, it is also quite likely that systemic activation of the coagulation cascade contributes to the prothrombotic state associated with advanced atherosclerosis. This is consistent with studies showing that atherosclerosis is associated with increased risk for venous thromboembolic disorders, as well as arterial thrombosis.[9] Elevated levels of circulating D-dimer and thrombin-antithrombin complexes have been reported in patients with ACS and D-dimer levels tend to track with hsCRP. Large-scale population studies have identified elevated fibrinogen and factor VIII levels as risk factors for atherosclerosis. Recent studies suggest that a key initiator of thrombin generation in these settings is circulating TF (see Fig. 146-8) in the form of TF-expressing MPs. MPs are vesicular fragments that bud off from cells during either activation or apoptosis. They are 200 to 1000 nm in size and possess different antigenic properties depending on the cell from which they are derived. MPs can be generated from platelets, monocytes, erythrocytes, leukocytes, or endothelial cells during vascular injury and have been shown to become incorporated into developing thrombi in vivo. MPs, mostly of platelet origin, can be detected in the circulation of normal human subjects, but markedly increased numbers of circulating MPs have been reported in patients with a variety of inflammatory and prothrombotic disorders including ACS.[29]

MPs contribute to thrombus formation through several mechanisms. A general feature of MP generation is loss of membrane asymmetry so that anionic phospholipids normally oriented in the inner membrane leaflet become exposed on the outer leaflet. Surface-exposed phosphatidylserine (PS) is a site for catalytic assembly of the prothrombinase complex and thrombin generation. Furthermore, PS on the surface of MP also has the capacity to bind to platelet CD36 and enhance platelet reactivity via the same mechanism as does oxLDL.

It is important to note that MPs derived from some cells (e.g., monocytes, macrophages, smooth muscle cells, and tumor cells) are a source of circulating TF. An important mechanistic link between atherogenesis and thrombosis may be oxLDL, which in vitro can induce TF-positive MP generation from blood-derived monocytes.[33] Of interest, a recent large clinical trial testing the efficacy of statins in subjects with normal LDL, but elevated levels of hsCRP, showed that rates of venous thrombosis, as well as coronary events, were significantly decreased.[9] In animal models, statins decrease circulating levels of oxLDL and also decrease circulating MP levels and levels of other prothrombotic and proinflammatory biomarkers, even in the absence of lowering cholesterol, suggesting that oxLDL-mediated prothrombotic activities may be important targets for thromboprevention in patients with atherosclerosis.[33] These studies also support those showing that statins may have antiinflammatory and antithrombotic activities independent of lipid lowering. Since HMGCoA reductase is also the limiting step in biosynthesis of isoprenoids, it has been postulated that statins may dampen signaling pathways mediated by small molecular weight G proteins (e.g., Ras) in which membrane targeting by protein isoprenylation is required (see Fig. 146-2).

In mice, the contact activating system and intrinsic coagulation cascade have been shown to participate in arterial thrombosis after injury and to have proatherogenic properties.[30] Targeting these systems is attractive in that patients with known deficiencies in factor XII or contact system proteins have no obvious phenotype and do not have a bleeding diathesis, thus presumably an antithrombotic effect could be achieved without altering normal hemostasis.

CROSS TALK BETWEEN COAGULATION AND INFLAMMATION SYSTEMS IMPACT ATHEROGENESIS

As noted previously, atherosclerosis can be thought of as a chronic, low-grade inflammatory disease of the artery wall. Clinical studies based on biomarkers, such as hsCRP, MPO, and IL6, also suggest that advanced atherosclerosis is associated with a systemic state of chronic inflammation and that the degree of inflammation reflects the level of risk for major complications, possibly because the more inflamed the plaque, the more vulnerable the lesion. It is also now clear that mediators of inflammation, such as IL1, LPA, oxLDL, and circulating MPs may interact with platelets and the coagulation cascade to promote a hypercoagulable, prothrombotic state.[20] Furthermore, mediators of coagulation, such as thrombin, TF-factor VIIa complexes, and factor Xa, may contribute to the proinflammatory state by interacting with protease-activated receptors on endothelial cells and leukocytes. Activated platelets can contribute to inflammation by facilitating monocyte adhesion to endothelium and by secreting small molecules (ATP, pyrophosphates, and serotonin), cytokines and growth factors that have proinflammatory activity. Thus bidirectional cross-talk between the inflammation and coagulation systems serves to enhance each other and to promote atherosclerosis.

Not surprisingly, patients with systemic autoimmune inflammatory disorders, including rheumatoid arthritis, Wegener's granulomatosis, and lupus erythematosus have been shown to have accelerated atherosclerosis, as assessed by biomarkers, such as ultrasound evidence of carotid artery intima-medial thickening, as well as major cardiovascular events. Obesity, a risk factor for atherosclerosis, is now also known to be a systemic inflammatory disorder, with evidence of inflammation readily detectable within obese central adipose tissue. Obese patients also have elevated, circulating levels of coagulation and inflammation biomarkers, including plasminogen activator inhibitor-1 (PAI-1).

Given these observations, there has been renewed interest in exploring the use of antiinflammatory agents and antithrombotic agents to slow the progress of atherosclerosis. The approach has been tempered by clinical studies showing small increases in atherosclerotic complications in patients taking COX inhibitors (especially those with preferential activity against COX2), but this may relate to the specific target and the complication of altered eicosanoid production, perhaps changing the balance away from antiatherothrombotic end products, such as prostacyclin and resolvins, towards proatherothrombotic products, such as thromboxane, HETE, and lipoxins. Also, although aspirin and ADP receptor antagonists definitively reduce risk for major cardiovascular events, no studies have shown an impact on burden of atheroma. Nevertheless, novel agents targeted to more specific atherothrombotic pathways, such as chemokines, LDL oxidation, scavenger receptors, lipoxygenases, phospholipase 2, leukotrienes, selectins, and IL1 are being considered.

Although B cells are not prominent cellular constituents of plaque, humans and experimental animals often develop humoral immune responses to plaque constituents, particularly modified LDL. Antibodies against oxLDL may be protective, perhaps by facilitating clearance via pathways that do not lead to foam cell formation, and/or by interfering with oxLDL-mediated activation of circulating monocytes and platelets.[16] Based on these observations, passive immunization strategies against oxLDL are also being considered.

PLAQUE REGRESSION AND FUTURE DIRECTIONS

Finding pharmacologic approaches to decrease the amount of arterial plaque has proved to be an elusive goal. Intravenous ultrasound has shown that very aggressive lowering of LDL cholesterol with high-dose statins and extremely rigorous dietary alterations can halt plaque progression and, in some cases, cause some regression.[10] As noted previously, strategies to enhance RCT or to induce macrophage emigration from plaque are being developed and strategies to stabilize plaque by targeting the neovasculature, cellular apoptosis and efferocytosis are being considered. Specific antioxidant approaches based on fundamental understanding of the oxidation processes relevant to atherosclerosis remain viable as well. Finally, it is hoped that the large investment of research funds in large-scale genome-wide association studies (GWAS) may lead to identification of novel genes and pathways (such as miR-33a and PCSK9) that can be targeted with therapeutic or preventive effect. At present the most consistent data to come from GWAS identified a fairly large genomic region on chromosome 9p21 as a risk site, but specific gene identification has not yet been accomplished.

CHAPTER 147

STROKE

Michelle Canavan, Emer McGrath, and Martin O'Donnell

Stroke is the leading cause of acquired adult disability worldwide and the second most common cause of death after coronary heart disease. Primary stroke subtypes include ischemic stroke, intracerebral hemorrhage, and subarachnoid hemorrhage. Each stroke subtype has differing etiologies, outcomes, and management strategies. The past 20 years has seen considerable advances in diagnosis (emergence of widely available neuroimaging) and treatment of acute stroke. In addition, there is an increased awareness of the importance of covert stroke (stroke on neuroimaging in the absence of a history of acute clinical stroke). In this chapter, we provide an overview of stroke, with a primary focus on ischemic stroke, which is the most common cause of stroke worldwide.

DEFINITION

Stroke is defined by the World Health Organization (WHO) as "rapidly developing clinical signs of focal (at times global) disturbance of cerebral function, lasting more than 24 hours or leading to death with no apparent cause other than that of vascular origin." This definition is conventionally considered to include ischemic stroke, intracerebral hemorrhage, and subarachnoid hemorrhage. Clinical presentations lasting less than 24 hours are classified as transient ischemic attacks (TIA). Recently, it has been proposed that the definitions of stroke and TIA be revised to more tissue-based definitions—that is, based on the presence or absence of acute ischemia or hemorrhage on neuroimaging.

EPIDEMIOLOGY

Frequency

The WHO estimates that 15 million people suffer a stroke each year, and of these, 5 million people are left with permanent disability. In 2005, an estimated 5.7 million stroke-related deaths occurred, accounting for approximately 10% of total deaths worldwide. A small decrease in the age-specific stroke mortality rates has been projected from 2005 to 2030, which is largely due to a decline in mortality rates in high-income countries. However, considering the increasingly ageing population worldwide, the crude stroke mortality rates are projected to increase across all ages, from 89 per 100,000 in 2005 to an estimated 98 per 100,000 in 2030. In the absence of further effective population-based interventions, a projected 6.5 million stroke deaths will occur in 2015 and 7.8 million deaths in 2030. The increase in stroke mortality will be most marked in developing countries, where increases in stroke incidence are most prominent. Worldwide, stroke shows significant geographic variation, in terms of incidence (and temporal trends), case fatality, and case mix (i.e., stroke subtypes). A recent systematic review of population-based studies reported that from 1970 to 2008 a 42% decrease occurred in the incidence of stroke in high-income countries, compared with a more than 100% increase in the incidence of stroke in middle- and low-income countries. Therefore the projected increase in stroke incidence will occur largely in low- and middle-income countries.

Traditional Risk Factors for Stroke

Both ischemic stroke and intracerebral hemorrhage are associated with a number of potentially modifiable risk factors—namely, hypertension, smoking, diet, sedentary lifestyle, obesity, diabetes mellitus, and exercise. The INTERSTROKE study, which included 6000 participants from 22 countries, reported that 10 key risk factors were associated with 90% of the population-attributable risk (PAR) of ischemic stroke: hypertension, smoking, waist-to-hip ratio, diet, physical activity level, diabetes mellitus, alcohol intake, psychosocial stress and depression, cardiac causes such as atrial fibrillation, and ratio of apolipoprotein B to A1 (Table 147-1). Of these risk factors, five (hypertension, smoking, abdominal obesity, physical inactivity, and diet) were associated with 80% of the PAR for all strokes, and each of these five risk factors was important for both ischemic stroke and hemorrhagic stroke. Therefore a large proportion of stroke is potentially preventable, emphasizing the importance of developing effective population-based interventions to modify these key risk factors. Hypertension is the strongest risk factor for both ischemic stroke and intracranial hemorrhage, and it is arguably the most modifiable factor by lifestyle intervention (e.g., reduced salt intake) and medications.

PATHOBIOLOGY

Stroke can be primarily classified into ischemic stroke (Fig. 147-1) and hemorrhagic stroke. Hemorrhagic stroke is further subtyped into intracerebral hemorrhage (Fig. 147-2) and subarachnoid hemorrhage. In North America and Europe, approximately 87% of strokes are due to ischemia, with the remaining 13% occurring as a result of hemorrhage. In developing countries, a larger proportion of strokes are due to intracerebral hemorrhage.

Etiologic Classification of Ischemic Stroke

Unlike acute coronary syndrome, which is primarily due to large vessel atherosclerosis, the underlying mechanisms for ischemic stroke are more heterogeneous. The most commonly used etiologic classification is the Trial of Org 10172 in Acute Stroke Treatment (TOAST) classification system, which focuses on the pathophysiologic mechanism of ischemic stroke based on clinical features and the results of diagnostic investigations (brain imaging, cardiac investigations, and neurovascular imaging). The five etiologic subcategories in the TOAST classification system are large-artery stroke, cardioembolism, small-artery occlusion (or lacunar ischemic stroke), ischemic stroke of other determined etiology, and stroke of undetermined etiology.

Large-Artery Stroke

Large-artery stroke is usually a consequence of atherosclerosis in the extracranial (carotid or vertebral) and/or intracranial arteries (e.g., middle cerebral or basilar artery), with plaque rupture and

Table 147-1 Traditional Risk Factors for Ischemic Stroke

Risk Factor	OR (99% CI)
Hypertension (self-reported history)	2.37 (2.00-2.79)
Current smoking*	2.32 (1.91-2.81)
Diabetes mellitus	1.60 (1.29-1.99)
Ratio of apoB to apoA1	2.40 (1.86-3.11)
Obesity (waist-to-hip ratio)	1.69 (1.38-2.07)
Regular physical activity	0.68 (0.51-0.91)
Diet risk score	1.34 (1.09-1.65)
Alcohol consumption*	
1-30 Drinks per month	0.79 (0.63-1.00)
>30 Drinks per month	1.41 (1.09-1.82)
Psychosocial factors	
Psychosocial stress	1.30 (1.04-1.62)
Depression	1.47 (1.19-1.83)

Figure 147-1 CT OF BRAIN WITH RIGHT INTRACEREBRAL HEMORRHAGE.

superimposed thrombus formation. Ischemic stroke may result from artery-to-artery thromboembolism with distal occlusion or, less commonly, by acute occlusion with resultant hypoperfusion (e.g., watershed infarction). Large-vessel atherosclerosis accounts for about 20% of all ischemic stroke in high-income countries and is predominantly extracranial in origin. Intracranial atherosclerosis has been reported to account for as high as 33% to 50% of ischemic strokes in parts of Asia (e.g., China and Thailand), but it is a less common cause of ischemic stroke in North America and Europe. Arterial dissection, the third leading cause of ischemic stroke in young people, can lead

Figure 147-2 CT OF BRAIN WITH LEFT HEMISPHERIC ISCHEMIC STROKE.

to ischemic stroke by either local occlusion or distal thromboembolism. Predisposing factors for dissection are trauma and underlying arteriopathies, such as fibromuscular dysplasia. Less common large-vessel mechanisms of ischemic stroke include Moyamoya disease, Fabry disease, and large vessel arteritis (e.g., Takayasu arteritis and giant-cell arteritis).

Cardioembolism

This mechanism is responsible for approximately 14% to 30% of all ischemic strokes, with marked regional variations. There are a number of conditions that predispose to cardioembolism; emboli may originate from precardiac sources in the venous system (e.g., paradoxical embolism), intracardiac sources (e.g., atrial fibrillation) or postcardiac sources (e.g., aortic arch disease).

Precardiac. Paradoxical emboli are proposed to occur when emboli that arise in the venous circulation (e.g., from a deep vein thrombus) cross into the arterial circulation through a patent foramen ovale (PFO) or atrial septal defect (ASD), or through a pulmonary arteriovenous malformation (AVM). PFO is a common finding in the general population; occurring in about 20% of people have this finding. A number of observational studies have reported an association between first ischemic stroke and PFO, particularly in younger patients, but a PFO has not been shown to be a risk factor for recurrent ischemic stroke. An atrial septal aneurysm, which is a protrusion of part of the atrial septum through the fossa ovalis into the right and/or left atrium, is associated with an increased risk for ischemic stroke, especially in association with a PFO.

Intracardiac. Left-sided cardiac sources of emboli include left atrial thrombus secondary to atrial fibrillation or flutter; left ventricle thrombus subsequent to a transmural myocardial infarction, or akinetic segments of myocardium with a low ejection fraction; cardiac tumors such as left atrial myxoma; and abnormalities of the mitral valve (both native and artificial). Atrial fibrillation or flutter is a significant risk factor for stroke, and it is associated with a fivefold increase in risk. In North America and Europe, about 25% of all ischemic strokes are attributed to atrial fibrillation, a proportion that increases with advancing age. After acute myocardial infarction, mural thrombi can arise as a result of the presence of left ventricular aneurysms, akinetic segments of the left ventricular myocardium, or

new-onset atrial fibrillation or flutter. Congestive heart failure is also an independent risk factor for stroke and is associated with a two- to threefold increase in the relative risk for ischemic stroke.

Valvular heart disease may involve native (e.g., rheumatic) or prosthetic heart valves. Of native valvular disease, mitral stenosis has the strongest association with ischemic stroke; mitral annular calcification and mitral valve prolapse have weaker associations. Mitral stenosis is commonly associated with atrial fibrillation, which further increases the risk of ischemic stroke. Emboli can also arise from valvular vegetations in nonbacterial thrombotic endocarditis or infective endocarditis. Mechanical mitral and aortic valves are associated with a sufficiently high risk for ischemic stroke that indefinite oral anticoagulant therapy is indicated; the risk for stroke is highest with mechanical mitral valves. Rheumatic heart disease still accounts for half of all cases of endocarditis in some regions of the world (e.g., India and Africa). Several epidemiologic studies have shown a link between ischemic stroke and *Trypanosoma cruzi* infection (Chagas disease) in South America.

Postcardiac. Postcardiac sources of embolism include atherosclerotic plaques in the aortic arch, proximal to the left subclavian artery; atheromatous debris or platelet emboli arising from these plaques may enter the cerebral circulation, leading to an ischemic stroke. The prevalence of severe atheromata of the aortic arch (>4 mm) in patients with ischemic stroke is approximately 30%, and their presence is associated with a fourfold increase in the risk for ischemic stroke and peripheral embolism. Although anatomically a large vessel source, aortic arch disease is usually included in cardiac causes of ischemic stroke, as it is most often identified by transesophageal echocardiography.

Small-Artery Occlusion

Approximately 20% of all ischemic strokes are due to lacunar or small-vessel infarcts. Lacunar infarcts are the result of occlusion of small, deep-penetrating arteries, such as the lenticulostriate branches of the anterior cerebral and middle cerebral arteries. The terminal pathophysiologic mechanism underlying small artery occlusion is believed to be local thrombosis secondary to microatheroma (lipid-laden macrophages, cholesterol deposits, and subintimal fibroblast proliferation) and lipohyalinosis (the intermediate stage between fibrinoid necrosis and microatheroma, which has characteristics of both arterial atheromatous lipid deposits and arteriolar [hyalinization] disease). Growing evidence supports a concept that damage to the glycocalyx by factors such as hyperglycemia, hypertension, and smoking contributes to vascular endothelial damage. Other causes of small-artery occlusion include microemboli from atherosclerotic plaques, polycythemia rubra vera, antiphospholipid antibodies, amyloid angiopathy, cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL), cerebral autosomal recessive arteriopathy with subcortical infarcts and leukoencephalopathy (CARASIL), Sneddon syndrome, and various types of small-vessel arteritis. The combination of mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes (MELAS) is an inherited progressive disorder characterized by mitochondrial dysfunction and onset of stroke, typically before the age of 40. The mitochondrial angiopathy hypothesis suggests that the lesions are secondary to ischemia, which is caused by mitochondrial and vascular dysfunction in small cerebral arteries.

Ischemic Stroke of Other Determined Etiology

Cerebral Venous Sinus Thrombosis. Cerebral venous sinus thrombosis accounts for less than 1% of ischemic strokes and typically affects younger people. The superior sagittal, transverse and cavernous sinuses are those most commonly affected by thrombosis. Venous thrombosis in these sites results in localized edema and venous infarction, which often becomes hemorrhagic and may raise intracranial pressure. Reported risk factors for cerebral venous sinus thrombosis include inherited thrombophilias; acquired prothrombotic states such as antiphospholipid antibodies, pregnancy, and the puerperium; infections such as otitis, sinusitis, and mastoiditis; chronic inflammatory conditions such as Wegener granulomatosis and sarcoidosis; trauma such as head injury, dehydration, or injury to the jugular veins or sinuses during neurosurgical procedures.

Intracerebral Hemorrhage. Intracerebral hemorrhage accounts for approximately 10% to 15% of all strokes (a larger proportion is reported in middle- and low-income countries) and can be classified as either primary or secondary, depending on the underlying cause. Primary intracerebral hemorrhage accounts for about 80% to 90% of cases and is the result of spontaneous rupture of small intracerebral blood vessels, usually those damaged by chronic hypertension (and other vascular risk factors) or amyloid angiopathy. Antithrombotic therapy, particularly anticoagulant therapy, is an important risk factor for intracerebral hemorrhage. Secondary intracerebral hemorrhage occurs as a result of vascular abnormalities (e.g., ruptured saccular aneurysm, arteriovenous malformation), tumors (e.g., cavernous angioma, intracerebral neoplasm), impaired coagulation (e.g., due to oral anticoagulant drug use or bleeding disorders such as hemophilia or von Willebrand disease), hemorrhagic transformation of ischemic stroke, septic emboli, vasculitis, Moyamoya disease, or alcohol and/or illicit drug use (e.g., cocaine, amphetamines).

Subarachnoid Hemorrhage. Subarachnoid hemorrhage refers to bleeding within the subarachnoid space, which is the space between the arachnoid and pia mater. It accounts for about 5% of all strokes and is most commonly caused by rupture of an intracranial aneurysm (approximately 80% to 85% of cases). Idiopathic nonaneurysmal perimesencephalic hemorrhage accounts for about 10% of cases, whereas the remaining 5% are due to rare disorders, such as inflammatory lesions of cerebral arteries (e.g., mycotic aneurysm, polyarteritis nodosa, primary angiitis), noninflammatory lesions of intracerebral vessels (e.g., arterial dissection, cerebral arteriovenous malformations, cerebral amyloid angiopathy, cerebral venous thrombosis, Moyamoya disease), vascular lesions of the spinal cord (e.g., saccular aneurysm of the spinal artery, spinal arteriovenous malformation), coagulopathy (e.g., hemophilia, von Willebrand disease), sickle cell disease, tumors (e.g., malignant glioma), trauma, and drug use (cocaine, anticoagulants).

Stroke of Undetermined Etiology

In some cases, the cause of stroke cannot be definitively determined and the stroke is classified as "stroke of undetermined etiology". A stroke may be classified in this category when one of the following two conditions are met: (1) an extensive evaluation is negative, that includes large vessel imaging and complete cardiovascular assessment or; (2) the diagnostic evaluation is incomplete. Clearly, the most important determinant of the proportion of patients labeled as cryptogenic is the extent of the diagnostic testing, which makes between-study comparisons difficult.

Covert Stroke

Clinically overt stroke is considered to represent only a fraction of all episodes of stroke. The advent of contemporary magnetic resonance imaging (MRI) sequences has identified a large burden of subclinical cerebrovascular disease, which includes covert infarction, white matter hyperintensities, cerebral atrophy, and microbleeds. Covert stroke is common; for example, a systematic review of eight population-based studies reported a prevalence of "silent" brain infarcts in the general older adult population of 8% to 28%. Moreover, covert stroke has been associated with an increased risk of cognitive decline, dementia, depression, and gait impairment. Accordingly, the term *covert* has been adopted to replace the term *silent.*

Hematologic Disorders and Ischemic Stroke

Inherited Thrombophilias

In general, studies have reported either no association or a modest association between inherited thrombophilias and ischemic stroke. Metaanalyses of observational studies have failed to demonstrate a significant association between the factor V Leidin mutation and ischemic stroke in adults, although some small case-control studies have reported an increased risk for ischemic stroke in women with the Factor V Leiden mutation using oral contraceptives. Two large prospective population-based studies failed to demonstrate a significant association between the prothrombin mutation G20210A and ischemic stroke risk, although a large metaanalysis of 19 case control studies reported a modest association. There is no evidence to support an association between protein C, protein S, or antithrombin deficiency and ischemic stroke in adults.

Antiphospholipid Syndrome

Antiphospholipid syndrome is reviewed in Chapter 143. Stroke is the main acute arterial thrombotic complication of antiphospholipid syndrome and is reported to be the initial clinical manifestation in 13% of patients subsequently diagnosed with antiphospholipid antibody syndrome. However, the overall association between antiphospholipid antibodies (in the absence of other feature of the syndrome) and ischemic stroke is less certain. Anticardiolipin antibodies have been associated with ischemic stroke in some studies, especially in young women, but not in others. The lupus anticoagulant is a more potent risk factor for ischemic stroke than are antiphospholipid antibodies. For example, in the RATIO (Risk of Arterial Thrombosis in Relation to Oral Contraceptives) study, the odds ratio for lupus anticoagulant was 43.1 (95% CI, 12.2-152.2) compared with an odds ratio of 2.3 (95% CI, 1.4-3.7) for anti–β_2-glycoprotein I antibodies, with no significant association reported for anticardiolipin antibodies. Current American Heart Association (AHA) guidelines recommend oral anticoagulant therapy for the secondary prevention of ischemic stroke in patients with antiphospholipid syndrome; antiplatelet therapy is recommended for patients with ischemic stroke and anticardiolipin antibodies without other clinical features of antiphospholipid syndrome.

Sickle Cell Disease

This disorder is associated with an increased risk for stroke, particularly in those homozygous for the sickle cell gene. The risk for stroke is 11% at 20 years of age, increasing to 15% by 30 years and 24% by 45 years of age. Stroke may also be a clinical manifestation of heparin-induced thrombocytopenia. In one cohort study ($n = 906$), stroke was reported in 3.1% of patients with heparin-induced thrombocytopenia after 1 month of follow-up, with a reported 94% occurring due to ischemia.

Myeloproliferative Disorders

These disorders are associated with an increased risk for stroke. A large stroke registry reported that stroke was the presenting manifestation of a hematologic disorder in 1.3% (14/1099) of patients with acute stroke; myeloproliferative disorders were the most common hematologic disorder. Polycythemia vera is a risk factor for ischemic stroke. A randomized controlled trial of aspirin (100 mg daily) versus placebo in 518 patients with polycythemia rubra vera reported a rate of stroke (ischemic and hemorrhagic) of 1.2% in the aspirin group compared with 3.8% in the control group (RR 0.32; 95% CI, 0.09-1.16) over approximately 3 years of follow-up. Defective platelet function in patients with myeloproliferative conditions increases the risk for bleeding, and so intracerebral hemorrhage can also occur.

Thrombotic Thrombocytopenic Purpura

The risk for ischemic stroke is increased in this disorder, which is characterized by thrombocytopenia, microangiopathic hemolytic anemia, fever, renal failure, and neurologic abnormalities, including ischemic stroke.

Paraproteinemias

Waldenström macroglobulinemia, multiple myeloma, and POEMS syndrome (plasma-cell proliferative disorders, typically myeloma, polyneuropathy, and effects on many other organ systems) can be associated with an increased risk for stroke.

Genetic Risk Factors

A substantial body of evidence from twin, family, and animal studies supports a genetic contribution to stroke risk. However, very few genetic variants have shown convincingly positive associations with ischemic stroke in epidemiologic studies. According to a recent metaanalysis, the concordance rate for stroke is 65% higher in monozygotic twins than in dizygotic twins, ranging from 12.8% to 19.0% in monozygotic twins and 3.6% to 13.0% in dizygotic twins. Family history of stroke increases the risk for ischemic stroke by about 75%, and the presence of a first-degree relative with a history of hemorrhagic stroke is associated with a sixfold increase in the risk for hemorrhagic stroke. Rare Mendelian forms of stroke, such as CADASIL and CARASIL, have been described. These disorders manifest as small-vessel ischemic stroke. However, most single-gene disorders are uncommon and thus have limited impact on the wider population, despite their marked effect on individual risk in young populations. Beyond Mendelian forms of inheritance, very few common genetic variants have reliably been associated with sporadic, multifactorial cases of stroke.

CLINICAL MANIFESTATIONS

Clinical Presentation

Stroke is a clinical diagnosis, supported by the results of neuroimaging (CT or MRI of brain), but CT of the brain may be normal in patients with acute ischemic stroke. Stroke is characterized by a rapid onset, usually presenting with a focal neurologic deficit, lasting more than 24 hours or leading to death of a presumed vascular cause. Clinical episodes lasting less than 24 hours are classified as TIA. In about one-quarter of cases of TIA, there is evidence of ischemia on MRI imaging. Common presenting features include lateralizing weakness of the arms and/or legs, facial weakness, speech abnormalities (aphasia, dysarthria), visual loss (monocular visual loss or homonymous hemanopia), reduced level of consciousness, ataxia, diplopia, vertigo, and headache. A number of clinical conditions may mimic stroke. Among patients admitted to the hospital with a suspected stroke, only about two-thirds are subsequently diagnosed with stroke. Common mimics of stroke include migraine, seizures, syncope, hypoglycemia, primary or secondary brain tumors, transient global amnesia, or toxic-metabolic disturbances with delirium.

Ischemic Stroke Versus Intracerebral Hemorrhage

Patients with ischemic stroke and intracerebral hemorrhage have similar presentations. Although some clinical features are more typically associated with intracerebral hemorrhage (e.g., coma, neck stiffness, seizures, vomiting, and headache) than with ischemic stroke, neuroimaging is required to discriminate between ischemia and hemorrhage. Therefore CT or MRI imaging of the brain is mandatory in all patients with acute stroke.

Measuring Severity of Stroke

Many scales are available to determine stroke severity. Examples include the Scandinavian Stroke Scale, the Canadian Stroke Scale, and the National Institutes of Health Stroke Scale (NIHSS). Of these, the one most widely studied and most often used in clinical practices is the NIHSS. Other scales (e.g., Hunt and Hess; Fisher) are used to measure stroke severity in patients with subarachnoid hemorrhage.

Risk for Stroke After Transient Ischemic Attack

The ABCD2 score is a validated clinical prediction for stroke in patients with TIA. Points are scored for each of the following factors: age 60 years or older (1); blood pressure 140/90 mm Hg or higher on first evaluation (1); clinical symptoms of focal weakness with the spell (2) or speech impairment without weakness (1); duration of 10 to 59 minutes (1) or duration of 60 minutes or longer (2); and diabetes (1). In combined validation cohorts, the 2-day risks for stroke were 0% for scores of 0 or 1; 1.3% for scores of 2 or 3; 4.1% for scores of 4 or 5; and 8.1% for scores of 6 or 7. The presence of a new infarct on brain imaging in patients with a classic time definition of TIA is associated with a 2- to 15-fold increase in the subsequent short-term risk for stroke.

INVESTIGATIONS

CT of the Brain

Neuroimaging is required for valid distinction between ischemic and hemorrhagic stroke. CT of the brain is widely available in most acute hospital settings and reliably excludes intracerebral hemorrhage. On CT of the brain, early features of ischemia include loss of distinction between grey and white matter, sulcal effacement, loss of definition of the insula, and evolving areas of hypodensity. Scoring systems (e.g., ASPECT score) may be used to quantify the burden of ischemia, which predicts the risk for intracerebral hemorrhage in patients receiving thrombolysis. However, subarachnoid hemorrhage is not reliably excluded by CT alone; therefore a lumbar puncture and CSF analysis are also needed to reliably exclude this diagnosis in those with suspected subarachnoid hemorrhage who have a normal CT of the brain.

Magnetic Resonance Imaging

MRI is superior to CT for detecting acute ischemia, but in practice it is limited by patient contraindications and availability, especially in the acute setting. Diffusion-weighted imaging (DWI) may identify acute ischemia within 3 to 6 hours of symptom onset. For the diagnosis of intracerebral hemorrhage, MRI with GRE sequence has been reported to be similar to CT of brain (96% concordance).

Neurovascular Imaging

Extracranial and intracranial stenosis may be detected using ultrasound, CT angiography, MR angiography, or formal angiography. Ultrasound is a noninvasive, relatively inexpensive, and widely available imaging modality, but it is dependent on ultrasonographer experience and skill. Transcranial Doppler may be used to detect intracranial large vessel stenosis and has also been shown to risk-stratify patients with carotid stenosis by identifying those with microembolic signals. CT and MR angiography provide more precise measurements of large vessel stenosis than does ultrasound imaging.

Cardiac Workup

An electrocardiogram to identify atrial fibrillation/flutter or evidence of previous myocardial infarction should be performed in all patients. In addition, Holter/cardiac monitoring will reveal atrial fibrillation in a further 5% of patients with acute ischemic stroke. Transthoracic echocardiography has a low yield in patients without a previous cardiac history and with a normal cardiac examination. The routine use of transesophageal echocardiography is controversial, but this investigation is essential in patients with suspected endocarditis. A patent foramen ovale can be identified with a bubble study while performing transthoracic or transesophageal echocardiography. Although transesophageal echocardiography will detect potential etiologies of ischemic stroke in a relatively large proportion of patients, such as patent foramen ovale, atrial septal aneurysm, or aortic arch disease, the treatment implications of these findings are less certain (see later section on secondary prevention).

All patients should be screened for vascular risk factors, including hypertension, fasting lipid profile, serum glucose, and HbA1c. Coagulation profiles are required in all patients with acute ischemic stroke. Other investigations may include a complete blood count and erythrocyte sedimentation rate (ESR), as well as tests for C-receptive protein, antiphospholipid antibodies, lupus anticoagulant, troponin, blood cultures, antineutrophil cytoplasmic antibodies (ANCA), and antinuclear antibodies (ANA).

THERAPY

A complete review of the management of stroke is beyond the scope of this chapter. Instead, we will provide an overview of acute and chronic management of patients with acute stroke.

Reperfusion Therapy for Acute Ischemic Stroke

Thrombolysis for Acute Ischemic Stroke

Intravenous tPA is the most rigorously evaluated thrombolytic intervention in acute ischemic stroke. Current guidelines recommend administration of tPA to patients with acute ischemic stroke within 3 hours of symptom onset or within 3 hours since patient was last seen normal (e.g., patient presents with symptoms on waking). The recently published European Cooperative Acute Stroke Study (ECASS III) trial reported a reduction in stroke severity even when tPA was administered between 3 and 4.5 hours. A recent metaanalysis of trials (n = 3670) that evaluated tPA in acute ischemic stroke reported adjusted odds ratio for favorable 3-month outcomes of 2.55 (95% CI, 1.44-4.52) for tPA administration within 0 to 90 minutes, 1.64 (1.12-2.40) for 91 to 180 minutes, 1.34 (1.06-1.68) for 181 to 270 minutes, and 1.22 (0.92-1.61) for 271 to 360 minutes. The main complication of tPA is intracerebral hemorrhage. In the above metaanalysis, large parenchymal hemorrhage was seen in 96 (5.2%) of 1850 patients assigned to tPA compared with 18 (1.0%) of 1820 controls (Table 147-2). An ongoing randomized controlled trial (International Stroke Trial [IST]-3) is evaluating tPA administered within 6 hours of symptoms onset in 3100 patients with acute ischemic stroke; this trial should provide key information on the effectiveness of tPA administration between 3 and 6 hours and in older adults.

Intraarterial Thrombolysis

Intraarterial thrombolysis within 6 hours of acute ischemic stroke has been evaluated in three small clinical trials (n = 334). This treatment is associated with an increased odds of a good functional outcome. However, no trials have compared intraarterial thrombolysis with intravenous thrombolysis. Current guidelines suggest intraarterial thrombolysis within 6 hours of symptom onset for patients with a contraindication to intravenous thrombolysis and who have proximal

Table 147-2 Eligibility Criteria and Contraindications for Acute Thrombolysis in Acute Ischemic Stroke

ELIGIBILITY CRITERIA
Diagnosis of ischemic stroke causing measurable neurologic deficit
Neurologic signs not minor or isolated (caution to be exercised in treating patients with major deficits)
Onset of symptoms <3 hours before beginning treatment (some guidelines suggest up to 4.5 hours)
Neurologic signs not clearing spontaneously
Symptoms of stroke not suggestive of subarachnoid hemorrhage
Patient and/or family members aware of potential risks and benefits of treatment
CONTRAINDICATIONS FOR THROMBOLYSIS
Evidence of intracranial hemorrhage on CT
Head trauma or prior stroke in previous 3 months
Myocardial infarction in previous 3 months
Gastrointestinal or urinary tract hemorrhage in previous 21 days
Arterial puncture at a noncompressible site in previous 7 days
Major surgery in previous 14 days
History of previous intracranial hemorrhage
Blood pressure elevated (systolic >185 mm Hg and diastolic >110 mm Hg)
Evidence of active bleeding or acute trauma (fracture) on examination
Taking an oral anticoagulant or, if anticoagulant being taken, INR ≥ 1.7
If received heparin in previous 48 hours, aPTT outside the normal range.
Platelet count ≤ 100 000 mm^3
Blood glucose concentration ≤ 50 mg/dL (2.7 mmol/L)
Seizure with postictal residual neurologic impairments
CT showing a multilobar infarction (hypodensity >1/3 cerebral hemisphere)

cerebral artery occlusions. However, limited access to interventional neuroradiology services has been a major limitation to the use of this intervention and to its evaluation in large-scale trials.

Mechanical Clot Retrieval

Mechanical thrombectomy has been evaluated in cohort studies but there are no randomized controlled trials to date.

Acute Stroke Unit

Organized stroke unit care in a dedicated, geographically identified ward with multidisciplinary teams that exclusively manage patients with stroke is associated with improved outcomes in patients with acute stroke. A metaanalysis of 26 trials ($n = 5592$) reported a reduction in death at 1 year (OR 0.86; 95% CI, 0.76-0.98) and death or dependency at 1 year (OR 0.82; 95% CI, 0.73-0.92). Unlike acute thrombolysis, stroke unit care is generalizable to the majority of patients with acute stroke. Beneficial results were independent of age, sex, or stroke severity and appeared to be more likely when the stroke unit was located in a separate geographic area within the hospital. Organized stroke care is associated with improved outcomes for several reasons, including early mobilization, reduced risk of medical complications such as aspiration pneumonia, fever prevention, and reduced frequency of urinary tract infections, falls, and delirium. Prompt evaluation of swallow function and compliance with speech pathology guidelines in relation to safe swallow practices have been shown to reduce the risk for aspiration pneumonia in stroke patients.

Blood Pressure in Acute Stroke

Although hypertension is the most important risk factor for both ischemic and hemorrhagic stroke, the optimal approach to managing elevated blood pressure in the acute setting remains uncertain. The recently published Scandinavian Candesartan Acute Stroke Trial (SCAST) randomized 2029 patients with acute stroke (ischemic or hemorrhagic) and systolic blood pressures of 140 mm Hg or higher to escalating doses of candesartan (4-16 mg on day 1 to days 3-7) or to placebo. No difference was observed in the rate of recurrent cardiovascular events, and there was a suggestion that lower blood pressures were associated with poorer functional outcome at 6 months. The Intensive Blood Pressure Reduction in Acute Cerebral Haemorrhage Trial (INTERACT), a phase II trial of patients with intracerebral hemorrhage and high blood pressure (150-220 mm Hg systolic), suggested that early intensive blood pressure reduction was safe and associated with reduced hematoma growth. A phase III trial (INTERACT II) is now underway to examine the effect of this blood pressure strategy on clinical outcomes.

Antithrombotic Therapy in Acute Ischemic Stroke

Based on the results of two large randomized controlled trials (IST and the Chinese Acute Stroke Trial [CAST]), aspirin reduces the risk for recurrent stroke and mortality in patients with acute ischemic stroke. The risk of the composite outcome of recurrent stroke of any type (including hemorrhagic stroke and hemorrhagic transformation of ischemic stroke), and death from any cause was reduced by 11% during the treatment period. In general, treatment doses of parenteral anticoagulants are not indicated in acute ischemic stroke, other than in patients with cerebral venous sinus thrombosis. Although treatment doses of heparins are commonly used in patients with extracranial dissection, clinical trials comparing antiplatelet therapy with anticoagulant therapy in these patients have not been performed.

Carotid Endarterectomy and Stenting

The European Carotid Surgery Trial (ECST) and the North American Symptomatic Carotid Endarterectomy Trial (NASCET) are the largest trials to evaluate carotid endarterectomy (CEA) in patients with recent ischemic stroke and TIA. Based on the results of these trials, current guidelines recommend CEA in patients with 70% to 99% stenosis of the ipsilateral carotid artery, provided that the perioperative morbidity and mortality are estimated to be less than 6%. Although patients with stenosis of 50% to 69% also benefit from CEA, the benefit is more modest and CEA is only recommended for selected patients based on age, comorbidities, time from stroke/TIA onset, and operative risk. Time from symptom onset to CEA is the primary determinant of the absolute risk reduction obtained with the procedure, with most of the benefit realized when CEA is performed within 2 weeks of presentation. Carotid stenting, which has been compared with CEA in patients with recent stroke and TIA, is not superior to CEA. However, although CEA remains the gold standard for patients with symptomatic significant carotid stenosis, carotid stenting is an alternative for patients with over 70% stenosis who are considered unsuitable for CEA (e.g., estimated to be at high operative risk).

Intracranial Stenting

For patients with large-vessel intracranial disease, a recent clinical trial (SAMMPRIS) did not report a benefit of endovascular stenting (plus aggressive medical management) over aggressive medical management alone. This trial was stopped early because of a higher rate of stroke and death at 30 days in the endovascular group.

Prevention of Venous Thromboembolism

See Chapter 144 for this discussion.

Acute Management of Intracerebral Hemorrhage

Management of intracerebral hemorrhage includes both medical and surgical components. Initial strategies include monitoring in an intensive care setting in appropriate patients, intubation in those with reduced consciousness, discontinuation of antithrombotic therapy and immediate reversal of anticoagulant therapy (see Chapter 151), administration of antipyretic medications to febrile patients, insulin for hyperglycemia, and venous thromboembolism prophylaxis (e.g., compression stockings). Raised intracranial pressure (ICP) can occur as a result of the hemorrhage itself or because of secondary edema. Management of increased ICP includes elevating the head of the bed to 30 degrees, analgesia, and sedation. More aggressive therapies include osmotic diuresis with mannitol, drainage of cerebrospinal fluid using a ventricular catheter (ventriculostomy), hyperventilation, and neuromuscular blockade. Antiepileptic therapy should be administered to control seizures in patients with intracerebral hemorrhage. Seizure prophylaxis is not recommended in current guidelines. The Surgical Trial in IntraCerebral Haemorrhage (STICH trial; n = 1033), which compared early surgery with medical management in patients with intracerebral hemorrhage within 72 to 96 hours of onset, failed to demonstrate a significant benefit of early surgery. However, uncertainty remains in some patient groups, and current guidelines suggest craniotomy for those with a lobar bleed of more than 30 mL located within 1 cm of the brain surface. Surgical evacuation of intracerebral hemorrhages is recommended for patients with cerebellar hemorrhages over 3 cm in diameter who have evidence of deterioration, brainstem compression, or hydrocephalus. Ventriculostomy with external drainage may be required for patients with intraventricular extension of an intracranial hemorrhage and a deteriorating level of consciousness. Although initial studies with recombinant factor VIIa (rFVIIa) yielded promising results, such treatment failed to reduce in death or severe disability at 90 days compared with placebo in a large phase III study, and higher-dose FVIIa administration (80 mcg/kg) was associated with a higher rate of serious adverse arterial thromboembolic events (myocardial infarction or cerebral infarction) in the 80 mcg/kg group compared with placebo. Current guidelines suggest that rFVIIa is investigational and should not be used outside of a clinical trial.

Stroke Rehabilitation

Stroke rehabilitation should commence as soon as possible. Animal models of neuroplasticity suggest that training results in upregulation of growth-promoting factors primarily in the first 4 weeks after the stroke, but recovery can continue for months or years after stroke. Good outcomes from stroke rehabilitation are associated with high patient (and family) motivation and engagement. Substantial evidence supports well-coordinated multidisciplinary team care (nursing, physiotherapy, occupational therapy, speech therapy, dietetics, and social work) as the basis for delivery of stroke rehabilitation. This care can be provided in the stroke unit setting or by early supported discharge teams in the patient's own home. Both strategies have been shown to improve independence in stroke patients. For older patients with stroke, physical rehabilitation in long-term care facilities is effective and has been shown to improve independence.

Chronic Secondary Prevention of Ischemic Stroke

Case Study

A 72-year-old man presented with right-sided weakness and expressive aphasia 4 weeks ago. CT scan of the brain revealed an ischemic stroke in the left hemisphere. He was admitted to a stroke unit, and after completing a rehabilitation program, he was discharged home. Etiologic investigations included ultrasound of carotids (<20% stenosis), Holter monitor (no arrhythmia), and transthoracic echocardiogram with bubble study, which revealed a small patent foramen ovale. He is known to have hypertension; his serum glucose level and HbA1c were normal. He was initiated on aspirin at the time of diagnosis. His blood pressure in the clinic today is 152/92 mm Hg, and he is currently taking perindopril (8 mg daily). His fasting LDL level was 140 mg/dL.

Antithrombotic Therapy

Acceptable regimens include aspirin, clopidogrel, or aspirin-dipyridamole; any one of these is recommended by current guidelines for secondary prevention of noncardioembolic ischemic stroke. The combination of aspirin plus clopidogrel should not be used because this regimen was not superior to clopidogrel alone in the MATCH trial and was associated with a higher risk of bleeding. If the patient had atrial fibrillation or a mechanical heart valve, oral anticoagulation therapy should be given for secondary prevention of ischemic stroke (see box on When Should Warfarin Be Started After Acute Ischemic Stroke in Patients With Atrial Fibrillation?). Although the new oral thrombin or factor Xa inhibitors (see Chapter 151) have not been specifically evaluated for secondary prevention in patients with atrial fibrillation, they are likely to provide the same risk reduction compared with warfarin as they do in primary prevention. Oral anticoagulants are not superior to aspirin for secondary prevention of stroke in patients with noncardioembolic ischemic stroke (WARSS and ESPRIT trials) or in patients with intracranial stenosis (WASID trial).

Lipid Modification

Current guidelines recommend statin therapy in patients with LDL levels of 100 mg/dL or higher. The SPARCL trial, which randomized 4731 patients with stroke/TIA and LDL levels between 100 and 190 mg/dL to atorvastatin 80 mg daily or placebo, reported a 16% reduction in recurrent stroke over approximately 5 years of follow-up with statin therapy (HR 0.84; 95% CI, 0.71-0.99).

Blood Pressure

The largest secondary prevention blood pressure study was the PROGRESS trial, which evaluated the use of perindopril plus indapamide. The combination reduced blood pressure by 12/5 mm Hg

When Should Warfarin Be Started After Acute Ischemic Stroke in Patients With Atrial Fibrillation?

The optimal timing of introduction of oral anticoagulation in patients with acute ischemic stroke and atrial fibrillation is uncertain, and there are variations in clinical practice. We initiate all patients on aspirin in the acute setting, and we base the timing of warfarin on the severity of stroke, the size of infarction, and comorbidities that may increase the risk for intracerebral hemorrhage. In patients with acute transient ischemic attack or in those with a minor ischemic stroke who do not have a large area of acute infarction, we usually initiate warfarin within 1 to 2 days, provided there are no other contraindications. For those with moderate or severe stroke with a moderate to large area of infarction, aspirin without anticoagulant therapy is recommended in the acute phase. Warfarin may be initiated 5 to 7 days after stroke onset—after excluding hemorrhagic transformation on neuroimaging. In patients with large infarcts or in those with evidence of hemorrhagic transformation, progressing stroke, or uncontrolled hypertension, initiation of warfarin should be delayed beyond 14 days. We stop aspirin once a therapeutic anticoagulant effect with warfarin is achieved, unless there is an indication for the combination of aspirin plus warfarin (e.g., coronary stent).

and stroke risk by 43% (CI 30%-54%). The combination of perindopril plus a diuretic produced greater reductions in blood pressure and larger risk reductions than therapy with perindopril alone. Current guidelines recommend a target blood pressure of 140/90 mm Hg or less.

Patent Foramen Ovale Closure

The recent CLOSURE trial failed to demonstrate a benefit of patent foramen ovale closure after acute ischemic stroke, and the risk for new atrial fibrillation was higher in the closure group than in those managed medically. Studies evaluating other closure devices after ischemic stroke are ongoing.

Lifestyle Modification

Lifestyle modification remains a cornerstone of stroke prevention. These measures include smoking cessation, moderate physical activity, weight reduction in those who are overweight or obese, a heart-healthy diet with increased fruit and vegetable intake, reduced salt intake in those who consume high-salt diets, and moderate alcohol consumption.

PROGNOSIS

Prognosis after stroke depends on the age of the patients, the etiology of the stroke, the severity of the neurologic deficits (and consequent level of dependence), and the burden of comorbid conditions. In a large cohort study that included 10,399 patients hospitalized with stroke in the United States, the 1- and 4-year mortality rates were 24.5% and 41.3%, respectively, and the 1- and 4-year risks of recurrent stroke were 8.0% and 18.1%, respectively. In that study, and in others, mortality was higher in patients with intracerebral or subarachnoid hemorrhage. Early causes of death are usually neurologic in origin (cerebral edema, raised intracranial pressure) or medical complications of dependence (e.g., aspiration pneumonia). On longer-term follow-up, most deaths are cardiovascular in origin. Of patients who survive stroke, two-thirds are left with chronic disability. In addition, patients with stroke are at increased risk for myocardial infarction, hip fracture, pneumonia, and repeated hospital admission. Other common chronic complications of stroke include seizure disorders, cognitive impairment and dementia, depression, and chronic pain syndromes (e.g., central post-stroke pain).

FUTURE DIRECTIONS

Most of our knowledge about the epidemiology of stroke comes from studies in North America and Europe, with considerably less data derived from middle and low-income countries. Ongoing large epidemiologic studies (e.g., INTERSTROKE) will provide data on regional variations in the importance of risk factors for stroke. In addition, a number of large ongoing epidemiologic collaborative studies (International Stroke Genetics Consortium) will clarify the role of genetics in the pathogenesis of stroke. Population-based interventions to reduce the burden of stroke will be an important focus of future research and will include interventions to reduce excess salt intake and the use of combination cardioprotective therapies (e.g., Polycap) in high-risk populations. In patients with TIA and minor ischemic stroke, a phase II trial (FASTER) suggests that the combination aspirin plus clopidogrel may be superior to aspirin alone; a phase III trial will clarify the role of dual antiplatelet therapy in this setting. The Efficacy of Nitric Oxide in Stroke (ENOS) trial is evaluating the effectiveness of transdermal glyceryl trinitrate in acute stroke. Other ongoing trials will determine the role of acute interventions designed to reduce the severity of stroke (e.g., albumin, hypothermic interventions, magnesium, or erythropoietin). For secondary prevention, ongoing trials will help to clarify the optimal antithrombotic therapy and target blood pressure for patients with small-vessel disease (Secondary Prevention of Small Subcortical Strokes [SPS-3]), the utility of closure devices in patients with a patent foramen ovale, and the usefulness of anticoagulant therapy for aortic arch disease (Aortic Arch-Related Cerebral Hazard [ARCH] trial).

CHAPTER 148

ACUTE CORONARY SYNDROMES

John W. Eikelboom and Jeffrey I. Weitz

Acute coronary syndromes (ACS) lead to millions of hospital admissions worldwide each year and are a leading cause of death. Antithrombotic therapies are a cornerstone in the immediate and long-term management of ACS, reducing the risk of myocardial infarction (MI) and death in both medically and invasively managed patients. This chapter reviews fibrinolytic, antiplatelet, and anticoagulant therapies in the treatment of patients with ACS and provides a practical guide to several common hemostatic and thrombotic problems encountered in this patient population.

CLASSIFICATION

The clinical classification of ACS is based on the electrocardiogram (ECG) at the time of presentation and on blood levels of cardiac biomarkers (creatine kinase, troponin). Patients with ST-segment elevation on the ECG and elevated cardiac biomarkers are diagnosed with ST-segment elevation MI (STEMI). Patients with non–ST-segment elevation (NSTE) ACS are subdivided according to whether or not they have elevated blood levels of cardiac biomarkers; those with elevated cardiac biomarkers are diagnosed with non–ST-segment elevation MI (NSTEMI), and those without elevated cardiac biomarkers are diagnosed with unstable angina (UA).[1-3]

PATHOPHYSIOLOGY

Atherothrombosis plays a central role in the pathogenesis of ACS.[4] Hypertension, abnormal blood glucose levels, dyslipidemia, and toxins contained in tobacco cause endothelial injury. Lipid accumulation and the recruitment of macrophages, smooth muscle cells, and fibroblasts to the site of injury results in the formation of increasingly complex and unstable plaques with a necrotic core and fibrous cap. Disruption of the fibrous cap by shear forces and its degradation by enzymatic and cellular processes expose the plaque contents to the blood. Platelets adhere to exposed subendothelial proteins and become activated and aggregate. Exposed tissue factor promotes thrombin generation on cellular surfaces, further promoting the formation of a platelet-fibrin thrombus that can occlude coronary blood flow. These processes are described in more detail in Chapter 146.

The clinical manifestations of coronary atherothrombosis are influenced by the extent and duration of obstruction to blood flow and the presence or absence of a collateral circulation. Patients with minor plaques that do not significantly impair blood flow generally remain asymptomatic. Patients with significant flow-limiting plaques may develop ischemic symptoms (e.g., chest pain, breathlessness) during exertion when myocardial oxygen demand exceeds supply. Patients with acute plaque rupture with superimposed thrombus formation that completely obstructs coronary blood flow typically present with STEMI unless there is an adequate collateral circulation. If obstruction to blood flow is transient or partial, patients typically present with NSTE ACS. If myocardial ischemia results in ventricular fibrillation, sudden cardiac death supervenes.

ANTITHROMBOTIC MANAGEMENT

The goal of antithrombotic therapies in patients with ACS is to facilitate lysis of intracoronary thrombus and prevent new thrombus formation at the site of plaque disruption. Antithrombotic drugs are also used to prevent thrombus formation on catheters and stents and to prevent and treat left ventricular thrombus formation.

Although the pathophysiology is similar irrespective of whether patients present with STEMI or NSTE ACS, only STEMI patients benefit from immediate reperfusion therapy. Most patients with NSTEMI do not have an occluded infarct-related coronary artery. Instead, they develop infarction as a consequence of distal embolization of thrombus.

REPERFUSION THERAPY FOR ST-SEGMENT ELEVATION MYOCARDIAL INFARCTION

Effective approaches to coronary reperfusion include mechanical (primary percutaneous coronary intervention) and pharmacologic (fibrinolytic therapy) methods.

Primary Percutaneous Coronary Intervention

Primary percutaneous coronary intervention (PCI) is preferred over fibrinolytic therapy in patients with STEMI because it produces higher patency rates and does not cause intracranial bleeding. Unlike fibrinolysis, which only treats the thrombus, primary PCI also allows treatment of the underlying atherosclerotic plaque. However, many centers lack the facilities and expertise to perform urgent coronary interventions, and only a minority of STEMI patients worldwide is treated with primary PCI.[5,6] Patients undergoing primary PCI are routinely treated with anticoagulant and antiplatelet therapy (discussed in sections on antiplatelet therapy and anticoagulant therapy).

Fibrinolytic Therapy

Fibrinolytic drugs are plasminogen activators that initiate fibrinolysis by converting plasminogen to plasmin. Plasmin degrades fibrin resulting in clot lysis and recanalization of thrombotic occlusion. Restoration of coronary blood flow limits infarct size and improves myocardial function and survival.

The pharmacologic characteristics of the fibrinolytic drugs most commonly used in the management of ACS are summarized in Table 148-1. Streptokinase was the first agent to be evaluated in large-scale randomized controlled trials. A non–fibrin-specific agent, streptokinase, indirectly activates plasminogen, but the more fibrin-specific agents alteplase, reteplase, and tenecteplase directly convert plasminogen to plasmin. Reteplase and tenecteplase have longer half-lives than alteplase, enabling them to be given by double- or single-bolus injection, respectively, which simplifies administration. The direct-acting fibrinolytic agents are more fibrin specific than streptokinase because

Table 148-1 Pharmacologic Characteristics of Fibrinolytic Drugs Used in the Management of Patients With ST-Segment Elevation Myocardial Infarction

Characteristic	Streptokinase	Alteplase	Reteplase	Tenecteplase
Fibrin specificity*	–	++	+	+++
Dose	1.5 million units	100 mg	20 U	30-50 mg
Administration	Infusion over 30-60 minutes	Bolus 15 mg; then infusion 0.75 mg/kg (maximum, 50 mg) over 30 minutes, 0.5 mg/kg (maximum, 35 mg) over the next 60 minutes	Double bolus, 10 U over 2 minutes; then repeat 10 U bolus at 30 minutes	Single weight-adjusted bolus, <60 kg = 30 mg, 60 to 69 kg = 35 mg, 70 to 79 kg = 40 mg, 80 to 89 kg = 45 mg, ≥90 kg = 50 mg
Half-life (min)	18-23	3-4	18	20
Adjunctive antiplatelet therapy†	Aspirin	Aspirin	Aspirin	Aspirin
Adjunctive anticoagulant therapy	Heparin in patients at high risk of thromboembolism‡	Heparin 60 U/kg bolus (maximum, 4000 U); 12 U/kg/hr (maximum, 1000 U/hr)	Heparin 60 U/kg bolus (maximum, 4000 U); 12 U/kg/hr (maximum, 1000 U/hr)	Heparin 60 U/kg bolus (maximum, 4000 U); 12 U/kg/hr (maximum, 1000 U/hr)

*Less fibrin specificity is associated with more systemic fibrinogen depletion.
†Fibrinolytic drugs were evaluated on a background of aspirin, but the addition of clopidogrel to aspirin was subsequently shown to provide incremental benefit.
‡High-risk patients include those with large or anterior myocardial infarction, atrial fibrillation, known left ventricular thrombus, or previous thromboembolism.

they bind to fibrin where they convert fibrin-bound plasminogen to plasmin. Consequently, these agents produce a less marked systemic lytic state than streptokinase, which has no fibrin affinity. Avoidance of a systemic lytic state is an important potential advantage of fibrin-specific drugs because this can be expected to be associated with a lower risk of bleeding complications.

Initial trials with streptokinase established the efficacy of fibrinolytic therapy for reduction in the risk of MI and death; subsequent trials compared the efficacy and safety of newer fibrinolytic drugs with those of streptokinase or alteplase.

Streptokinase

Streptokinase is a single-chain polypeptide derived from β-hemolytic streptococcus cultures. After intravenous (IV) administration, streptokinase binds to plasminogen, and the resulting streptokinase–plasminogen enzymatic complex cleaves plasminogen to form plasmin. Because plasmin nonspecifically degrades circulating fibrinogen as well as fibrin, streptokinase induces a systemic lytic state. Streptokinase induces the formation of antistreptokinase antibodies and can cause allergic reactions, particularly with repeated administration. Severe reactions are rare, but rash, shivering, pyrexia, and mild hypotension occur in up to 10% of patients. It is uncertain whether neutralizing antibodies reduce the efficacy of streptokinase.

The GISSI-1 (Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardico 1) trial, which was conducted in 11,806 patients with STEMI, demonstrated that streptokinase (1.5 million units over 1 hour) compared with no lytic therapy significantly reduced 21-day in-hospital mortality (10.7% vs. 13.0%; $P = .0002$). A similar reduction in mortality was seen when the same dose of streptokinase was compared with no lytic therapy in 17,187 patient with suspected MI in the ISIS-2 (International Studies of Infarct Survival 2) trial (9.2% vs. 12.0%; $P < .00001$).

Alteplase

Alteplase is a recombinant tissue-type plasminogen activator that directly converts plasminogen to plasmin. Although more fibrin-specific than streptokinase, alteplase still induces a systemic lytic state. It has a circulating half-life of 3 to 4 minutes.

The ISIS-3 ($n = 41,299$) and GISSI-2 (20,891) trials found no benefit of alteplase over streptokinase, findings possibly explained by the suboptimal use of heparin in conjunction with a short-acting fibrinolytic agent (heparin was given subcutaneously after a delay of 4 to 12 hours) and lack of front-loading of alteplase. The GUSTO-1 (Global Utilization of Streptokinase and Tissue Plasminogen Activator to Treat Occluded Arteries 1) trial ($n = 41,021$) demonstrated that front-loaded alteplase (15 mg bolus, 0.75 mg/kg infusion [maximum, 50 mg] over 30 minutes and then 0.50 mg/kg [maximum 35 mg] over 60 minutes [maximum, 100 mg over 90 minutes]) plus IV heparin (5000 U bolus, 1000 U/hr, with the dose titrated to achieve an activated partial thromboplastin time [aPTT] of 60 to 85 seconds) compared with streptokinase (1.5 million units over 1 hour) with or without IV heparin, reduced 30-day mortality (6.3% vs. 7.3%; $P = .001$). The mortality benefits of alteplase were greatest in patients younger than the age of 75 years and in those with anterior MI. Despite its enhanced fibrin specificity, alteplase was not associated with less bleeding than streptokinase.

The greatest benefits of fibrinolytic therapy are seen in patients treated within 1 hour of symptom onset; there is a much smaller benefit or no benefit if treatment is commenced more than 6 hours after symptom onset.[7]

Reteplase

Reteplase is a second-generation nonglycosylated deletion mutant of alteplase. Reteplase is less fibrin specific than alteplase but has a longer half-life (18 minutes) that enables administration by bolus injection.

The INJECT trial ($n = 6,010$) demonstrated that reteplase and streptokinase were associated with similar 35-day rates of mortality (9.0% vs. 9.5%), in-hospital stroke (1.2% vs. 1.0%), and major bleeding (0.7% vs. 1.0%), although reteplase was associated with a twofold higher rate of intracranial bleeding (0.8% vs. 0.4%). The GUSTO-III trial ($n = 15,059$) demonstrated that reteplase (two 10 mg IV injections 30 minutes apart) and front-loaded alteplase were associated with similar 30-day rates of mortality (7.5% vs. 7.2%) and stroke (1.6% vs. 1.7%).

Tenecteplase

Tenecteplase is a third-generation multiple point mutant of alteplase. Tenecteplase has a half-life of 20 minutes and is given by single bolus injection. Tenecteplase is the most fibrin-specific fibrinolytic drug approved for clinical use.

The ASSENT-2 (Assessment of the Safety and Efficacy of a New Thrombolytic) study, which enrolled 16,949 STEMI patients, showed that tenecteplase and alteplase were associated with similar 30-day rates of mortality (6.2% vs. 6.2%) and stroke (1.8% vs. 1.7%). Tenecteplase did not increase the risk of intracerebral bleeding (1% vs. 1%) and reduced major noncerebral bleeding (4.7% vs. 5.9%; $P < .0002$), possibly reflecting its enhanced fibrin-specificity.

Adjunctive Antithrombotic Therapy in Patients Receiving Fibrinolytic Drugs

A compelling rationale exists to administer adjunctive antithrombotic therapy to STEMI patients treated with fibrinolytic therapy. Platelet-rich thrombi that form after plaque rupture are relatively resistant to lysis, and the use of concomitant antiplatelet therapy may help to promote clot lysis. Fibrinolytic drugs have a proaggregatory effect on platelets, and the plaque rupture site remains prothrombotic after successful reperfusion therapy. Evidence in support of the efficacy of adjuvant antiplatelet and anticoagulant therapy in patients with STEMI is summarized in the sections on antiplatelet and anticoagulant therapy.

Intracranial Bleeding

The most important side effect of fibrinolytic therapy is intracranial bleeding, which affects up to 1% of patients and, in the majority of cases, is either fatal or permanently disabling.[8] Risk factors for intracranial bleeding include increasing age (particularly patients older than the age of 75 years), history of prior stroke, uncontrolled blood pressure, female sex, and low body weight. Bolus dose fibrinolytic therapy may be associated with a higher risk of intracranial bleeding than fibrinolytic therapy administered by continuous IV infusion (see Table 148-2 and box on Case 1: Bleeding After Fibrinolytic Therapy).[9]

ANTIPLATELET THERAPY

Aspirin and the second-generation thienopyridine, clopidogrel, are the foundation antiplatelet therapies for the management of ACS. IV glycoprotein IIb/IIIa (GP IIb/IIIa) inhibitors were introduced during the 1980s. Although their use has fallen since the introduction of clopidogrel, they retain a role in high-risk ACS, particularly in STEMI patients undergoing primary PCI.[5,6,10] Many countries have recently approved the new $P2Y_{12}$ receptor antagonists prasugrel and ticagrelor as alternatives to clopidogrel. The pharmacologic characteristics of antiplatelet drugs commonly used in the management of ACS are summarized in Tables 148-3 (oral drugs) and 148-4 (IV GP IIb/IIIa inhibitors).

Oral Antiplatelet Drugs

Aspirin

Aspirin inhibits platelets by irreversibly blocking the platelet enzyme cyclooxygenase-1 (COX-1), thereby preventing the formation of thromboxane A_2, a potent platelet agonist and vasoconstrictor. Despite having a half-life of only 20 minutes, the antiplatelet effect of aspirin lasts for the lifetime of the platelet (5–10 days) because platelets are anucleate and lack the machinery to synthesize new enzyme.[11]

Multiple randomized trials have demonstrated the efficacy of aspirin for the prevention of recurrent MI, stroke, or death in patients with ACS.[12] The ISIS-2 investigators evaluated the efficacy and safety of aspirin in 17,187 STEMI patients who were also randomized to receive or not to receive fibrinolytic therapy. Aspirin (162 mg/day), compared with no aspirin, significantly reduced 35-day mortality

Case 1: Bleeding After Fibrinolytic Therapy

A 63-year-old man with a history of hypertension presents to a rural hospital with sudden onset of severe retrosternal chest pain. An ECG performed in the emergency department demonstrates 4-mm anterior ST segment elevation. The nearest hospital with a cardiac catheterization laboratory is more than 6 hours away. He is treated with aspirin (300 mg loading dose), clopidogrel (300 mg loading dose), and an IV infusion of front-loaded alteplase, with rapid resolution of pain and normalization of ST-segment elevation. Toward the end of the alteplase infusion, he complains of abdominal pain, becomes hypotensive, and develops melena. Hemoglobin is 10.2 g/dL, the aPTT is 89 seconds, the international normalized ratio (INR) is 1.7, and the fibrinogen level is below 100 mg/dL.

Aspirin and clopidogrel are held; the patient receives 10 units of cryoprecipitate and is started on an IV infusion of a proton pump inhibitor. He undergoes urgent upper gastrointestinal tract endoscopy with injection of a bleeding ulcer. He does not receive platelets because of concerns about the risk of recurrent MI. No further bleeding occurs, and after 48 hours, he resumes aspirin. Clopidogrel is restarted 1 week later after repeat endoscopy demonstrates a healing ulcer.

Comment

Fibrinolytic trials report a 1% to 6% incidence of major bleeding and a 10% incidence of moderate bleeding during the first 30 days. The most common sources of major bleeding are the gastrointestinal tract and procedure-related bleeding. The principles of management of major bleeding in STEMI patients treated with fibrinolytic therapy are summarized in Table 148-2. Steps include (1) stop antithrombotic therapies; (2) use local measures when possible to control bleeding; (3) draw blood to measure fibrinogen, prothrombin time (PT), aPTT, and possibly anti-Xa levels (to measure the anticoagulant effect of low-molecular-weight heparin) and to crossmatch blood; and (4) administer therapies to mitigate or reverse the effects of fibrinolytic, antiplatelet, and anticoagulant drugs.

The extent and duration of the lytic effects of fibrinolytic drugs is determined by their fibrin specificity. Whereas streptokinase produces profound and sustained depletion of fibrinogen (<100 mg/dL) that lasts for up to 24 to 48 hours, alteplase and other more fibrin-specific agents exert a less pronounced and more short-lived effect on fibrinogen levels. The aPTT and PT can be markedly prolonged in patients with hypofibrinogenemia. Normal coagulation can be restored by elevating fibrinogen level to at least 100 mg/dL. This can be readily achieved by infusing cryoprecipitate (recommended dose, 10 units). Fresh-frozen plasma also contains fibrinogen but requires administration of much larger volumes.

Platelet dysfunction caused by aspirin, clopidogrel, and fibrinolytic therapy cannot be specifically reversed, but infusion of donor platelets can help to restore platelet function. Platelet transfusion is generally reserved for patients with life-threatening bleeding because of concerns about the risk of recurrent MI. A single unit of single donor platelets can be expected to increase the platelet count by 50 to 60 $\times 10^9$/L. Even a small number (e.g., 10%-20%) of functional (nonaspirinated) platelets are sufficient to generate sufficient thromboxane to sustain normal platelet aggregation, but a much larger number of transfused platelets are need to overcome the antiplatelet effects of clopidogrel. In this case, bleeding was controlled with cryoprecipitate, and local measures and platelet infusions were not required.

Table 148-2 Management of Major Bleeding in Patients With ST-Segment Elevation Myocardial Infarction Treated With Fibrinolytic Therapy

Steps	Approach	Considerations
Stop treatment	Stop fibrinolytic drug Stop antiplatelet drugs Stop anticoagulant	Recovery of fibrinogen levels can take 24 to 48 hours after stopping streptokinase Antiplatelet effects of aspirin and clopidogrel last for life of platelet (5-10 days) Heparin has a half-life of about 40 minutes; LMWH has a half-life of 3 to 6 hours
Local measures	Local pressure Endoscopy and local injection* Embolization*	Sustained local pressure (e.g., for 30 minutes) may be required Can be used for upper or distal lower GI bleeding Used in rare situations such as life-threatening pulmonary or intra-abdominal bleeding
Laboratory evaluation	Fibrinogen PT and aPTT Anti-Xa level Crossmatch blood	Levels may be undetectable (<0.1 g/L) Results are uninterpretable if fibrinogen levels are low PT (INR) is elevated by warfarin; aPTT is prolonged by heparin but not with LMWH or fondaparinux Chromogenic assay for LMWH and fondaparinux Unaffected by low fibrinogen To restore blood volume and maintain hemoglobin
Reversal of fibrinolytic effect	Cryoprecipitate FFP	Recommended initial dose is 10 U; monitor by repeat fibrinogen level The half-life of fibrinogen is about 4 days Requires large volumes (e.g., 2 L) to restore fibrinogen levels
Reversal of antiplatelet effect	Platelet transfusion	Increases the number of functional platelets but does not reverse the antiplatelet effects of aspirin and clopidogrel Also see text under heading "Antiplatelet Therapy"
Reversal of anticoagulant effect	Protamine	Protamine reverses heparin and partially reverses LMWH; also see Table 148-6

aPTT, Activated partial thromboplastin time; *FFP,* fresh-frozen plasma; *GI,* gastrointestinal; *INR,* international normalized ratio; *LMWH,* low-molecular-weight heparin; *PT,* prothrombin time
*Also requires restoration of adequate hemostasis.

Reversible	No	No	No	Yes

ADP, Adenosine diphosphate; *bid,* twice daily; *COX,* cyclooxygenase.
*After loading dose.
†Increased antithrombotic benefit was seen after the first hour in patients enrolled in the COMMIT trial who did not receive a loading dose, but maximum effect is not seen until after 4 to 6 hours.

Table 148-4 Pharmacologic Characteristics of Intravenous Glycoprotein IIb/IIIa Inhibitors Used in the Management of Acute Coronary Syndrome

Characteristic	Abciximab	Eptifibatide	Tirofiban
Class	Fab fragment	Nonpeptide	Cyclic heptapeptide
Onset	Rapid	Rapid	Rapid
Drug half-life	10-30 min	2 hr	2.5 hr
Reversibility of platelet inhibition	Slow	Rapid	Rapid
Excretion	Unknown	40%-70% renal	50% renal

(9.4% vs. 11.8%; $P < .00001$) as well as nonfatal reinfarction (1.0% vs. 2.0%) and stroke (0.3% vs. 0.6%) without increasing bleeding. The Antithrombotic Trialists' Collaboration (ATTC) pooled the data from 15 randomized trials of antiplatelet therapy (predominantly aspirin) involving 19,302 patients with acute MI who were also treated with fibrinolytic therapy. Antiplatelet therapy given for a mean duration of 1 month compared with placebo or no antiplatelet therapy significantly reduced the composite outcome of MI, stroke, or death (10.4% vs. 14.2%; $P < .0001$).

At least four randomized controlled trials have demonstrated the efficacy of aspirin in patients with NSTE ACS. Pooled data from the four trials involving a combined total of 3096 patients indicate that aspirin compared with placebo or no aspirin significantly reduced the composite endpoint of MI, stroke, or vascular death (6.4% vs. 12.5%; $P = .0005$).

The efficacy and safety of aspirin have been evaluated in combination with dipyridamole in PCI patients in one randomized controlled trial involving 376 patients. Aspirin (300 mg) plus dipyridamole (75 mg), given orally three times daily (except during a 24-hour period around the time of the procedure when dipyridamole was given intravenously), compared with placebo, reduced the risk of MI by more than half (1.6% vs. 6.9%; $P = .01$). These results led to the adoption of aspirin as standard therapy for patients undergoing PCI.

The CURRENT OASIS-7 (Clopidogrel Optimal Loading Dose Usage to Reduce Recurrent EveNTs/Optimal Antiplatelet Strategy for InterventionS) trial explored the optimal dose of aspirin in 25,086 ACS patients with or without ST-segment elevation on the presenting ECG and included 17,263 patients undergoing early PCI.[13] After an initial aspirin loading dose, aspirin 300 to 325 mg/day and 75 to 100 mg/day were associated with similar rates of MI, stroke, or death at 30 days (4.2% vs. 4.4%), but the higher aspirin dose increased gastrointestinal bleeding (0.4% vs. 0.2%; $P = .04$). Based on these results, the optimal dose of aspirin for the management of patients with ACS (after an initial loading dose of 160-325 mg) appears to be 75 to 100 mg/day.

Clopidogrel

Clopidogrel is metabolized via the liver to form the active moiety that irreversibly blocks the platelet P2Y12 receptor to prevent adenosine diphosphate–induced platelet activation and aggregation. Similar to aspirin, the antiplatelet effect of clopidogrel lasts for the lifetime of the platelet. Clopidogrel is an effective antiplatelet drug for the prevention of MI and death when used in combination with aspirin but has a slow onset of action and a variable antiplatelet effect that may limit its effectiveness.

The COMMIT trial, which involved 45,582 patients with STEMI, all of whom were treated with aspirin (162 mg/day) demonstrated that 30 days of treatment with clopidogrel (75 mg/day) compared with placebo reduced the risk of MI, stroke, or death (9.2% vs. 10.1%; $P = .002$) with no increase in major bleeding (0.58% vs. 0.55%).[14] There was no age restriction in the COMMIT trial, and clopidogrel was given without a loading dose. In the CLARITY (Clopidogrel as Adjunctive Reperfusion Therapy) trial ($n = 3,491$), which was conducted in parallel with COMMIT, clopidogrel was given as a loading dose of 300 mg followed by 75 mg/day for 2 to 8 days and was compared with placebo in patients receiving fibrinolysis. Clopidogrel reduced the risk of MI or death (15% vs. 21.7%; $P < .001$). Consistent benefits of clopidogrel were demonstrated in the 1863 patients who underwent PCI after mandated angiography.

The CURE (Clopidogrel in Unstable Angina to Prevent Recurrent Events) trial, which involved 12,562 patients with NSTE ACS, all of whom were treated with aspirin (recommended dose 75-325 mg/day), demonstrated that a median of 9 months treatment with clopidogrel (300 mg loading dose followed by 75 mg/day) compared with placebo reduced the risk of MI, stroke, or death (9.3% vs. 11.4%; $P < .001$) at the cost of an increase in major bleeding (3.7% vs. 2.7%; $P = .001$).[15] Consistent benefits of clopidogrel were seen in the 2658 patients who underwent PCI irrespective of whether or not they underwent stenting.

Prompted by concerns that some patients achieve suboptimal inhibition of platelet function with conventional doses of clopidogrel, the CURRENT-OASIS 7 trial evaluated the efficacy and safety of a higher loading and maintenance dose of clopidogrel compared with standard dose clopidogrel in 25,086 patients with ACS referred for an invasive management strategy.[13] Clopidogrel, 600-mg loading dose followed by 150 mg/day for 6 days ("double-dose clopidogrel") and 75 mg/day for 23 days compared with a 300-mg loading dose and 75 mg daily thereafter ("standard dose clopidogrel") for 30 days were associated with similar rates of the primary outcome, MI, stroke, or vascular death (4.2% vs. 4.4%) and an increase in major bleeding (2.5% vs. 2.0%; $P = .01$). However, in the 17,263 patients who underwent PCI, double-dose compared with standard-dose clopidogrel reduced MI, stroke, or vascular death (3.9% vs. 4.5%; $P = .039$) and stent thrombosis (0.7% vs. 1.3%; $P = .0001$).

Prasugrel

Prasugrel is a third-generation thienopyridine that is more potent and has a more rapid onset of action than clopidogrel. Prasugrel is a prodrug, but unlike clopidogrel, it requires only single-step bioconversion to form the active metabolite that irreversibly blocks the platelet P2Y12 receptor.

The TRITON-TIMI 38 (Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition With Prasugrel–Thrombolysis In Myocardial Infarction 38) trial evaluated the efficacy and safety of prasugrel in 13,608 patients with ACS with or without ST-segment elevation who were undergoing PCI, all of whom were treated with aspirin (recommended dose, 75-162 mg/day).[16] Prasugrel (60 mg followed by 10 mg once daily) compared with clopidogrel (300 mg followed by 75 mg once daily) continued for a median of 14.5 months reduced the risk of MI, stroke, or cardiovascular death (9.9% vs. 12.1%; $P < .001$) and stent thrombosis (1.1% vs. 2.4%; $P < .001$) but did not reduce mortality and increased non–coronary artery bypass graft (CABG) major bleeding (2.4% vs. 1.8%; $P = .03$) as well as intracranial and fatal bleeding.

Ticagrelor

Ticagrelor is nonthienopyridine platelet P2Y12 receptor antagonist. Similar to prasugrel, ticagrelor is more potent and has a more rapid onset of action than clopidogrel, but unlike both clopidogrel and prasugrel, ticagrelor binds reversibly to the platelet P2Y12 receptor.

The PLATO trial evaluated the efficacy and safety of ticagrelor in 18,624 patients with ACS with or without ST-segment elevation.[17] Ticagrelor (180 mg loading dose followed by 90 mg twice daily) compared with clopidogrel (300 or 600 mg loading dose followed by 75 mg once daily) reduced the risk of MI, stroke, or vascular death by 16% (9.8% vs. 11.7%; $P < .001$) and produced a significant reduction in vascular death (4.0% vs. 5.1%; $P = .001$) and stent thrombosis (1.3% vs. 1.9%; $P = .009$). There was no increase in major bleeding (11.6% vs. 11.2%) or in intracranial or fatal bleeding, but ticagrelor increased non-CABG major bleeding (4.5% vs. 3.8%; $P = .03$).

Intravenous Antiplatelet Drugs

Glycoprotein IIb/IIIa Inhibitors

Three IV GP IIb/IIIa inhibitors are available for clinical use (see Table 148-4). Abciximab is a humanized version of a Fab fragment of a murine antibody directed against GP IIb/IIIa. Tirofiban is a nonpeptide tyrosine derivative that selectively binds to GP IIb/IIIa. Eptifibatide is a synthetic disulfide-linked cyclic heptapeptide with high specificity for GP IIb/IIIa.

The efficacy and safety of GP IIb/IIIa inhibitors has been extensively evaluated in patients with ACS. Meta-analysis restricted to trials ($n = 6$) involving at least 1000 patients suggests a modest effect of these agents for the prevention of MI, urgent revascularization, or vascular death in patients with NSTE ACS (10.8% vs. 11.8%; $P = .015$).[18] Pooled data from a meta-analysis of 16 randomized trials involving 10,085 STEMI patients undergoing primary PCI demonstrated that adjunctive GP IIb/IIIa blockade did not reduce 30-day mortality (2.8 vs. 2.9%; $P = 0.75$) or reinfarction (1.5 vs. 1.9%; $P = .22$) and increased major bleeding (4.1 vs. 2.7%; $P = .0004$). However, meta-regression analysis confirmed the impression from individual trials of a mortality benefit of IV GP IIb/IIIa inhibitors in those at highest risk (see boxes on Case 2: Stent Thrombosis and Case 3: Thrombocytopenia After Stenting).[19]

Case 2: Stent Thrombosis

A 49-year-old man with a history of type 2 diabetes presents with NSTEMI and undergoes PCI with placement of a drug-eluting stent in the left anterior descending coronary artery. He receives a 300-mg loading dose of aspirin and a 600-mg loading dose of clopidogrel and is discharged on aspirin 100 mg/day and clopidogrel 75 mg/day. He presents to the emergency department 3 weeks later with recurrent chest pain and anterior ST-segment elevation on the ECG. He denies missing any doses of clopidogrel. He is taken urgently to the cardiac catheterization laboratory, where a diagnosis of stent thrombosis is confirmed, and he undergoes repeat PCI with thrombus aspiration.

Prompted by concern about the possibility of "clopidogrel resistance," genotyping studies are performed and demonstrate heterozygosity for the CYP2C19 *2 loss-of-function allele. Clopidogrel is stopped, and he is started on prasugrel (10 mg once daily) instead. He is discharged on indefinite dual antiplatelet therapy with aspirin and prasugrel.

Comment

Stent thrombosis is a potentially life-threatening complication of PCI, affecting 1% to 2% of patients during the first year and presenting in almost all cases as death or MI.[20] Risk factors for stent thrombosis can be categorized as patient related, technical (procedure, stent, or lesion), or drug related. The single most important predictor of stent thrombosis is premature discontinuation of clopidogrel. High on-treatment platelet reactivity during clopidogrel therapy has also emerged as a predictor of stent thrombosis and is affected by clinical (e.g., age, diabetes, renal insufficiency) and genetic factors. Carriers of reduced function CYP2C19 alleles have low levels of the active metabolite of clopidogrel, diminished platelet inhibition, and an increased risk of stent thrombosis. Unlike clopidogrel, which undergoes two-step, cytochrome P450-dependen, metabolic conversion in the liver, prasugrel and ticagrelor are not affected by CYP polymorphisms and consistently produce a greater and more consistent level of platelet inhibition than standard clopidogrel doses. Higher doses of clopidogrel (e.g., 225 or 300 mg/day) in patients heterozygous for CYP2C19*2 alleles achieve levels of platelet inhibition similar to those seen with standard (75 mg) doses but have not been evaluated in clinical outcome studies.

The role of genetic testing to detect poor clopidogrel responders remains controversial. Although observational studies have demonstrated an independent association between CYP2C19 loss-of-function alleles and risk of stent thrombosis, analyses from multiple randomized controlled trials provide no evidence of an interaction between genotype and treatment for major cardiovascular events, including stent thrombosis.[21] It is reasonable to switch (without laboratory testing) patients who have experienced stent thrombosis despite clopidogrel therapy to one of the newer P2Y12 receptor antagonists (i.e., prasugrel or ticagrelor) that have been demonstrated to reduce the risk of stent thrombosis compared with clopidogrel.

Case 3: Thrombocytopenia After Stenting

A 65-year-old woman presenting with STEMI undergoes primary PCI with placement of a bare metal stent in her circumflex coronary artery. During the procedure, she receives an IV bolus of abciximab in addition to aspirin, clopidogrel, and heparin. A blood count performed after returning to the coronary care unit (within 6 hours of the procedure) reveals a platelet count of 6×10^9/L, which is confirmed on repeat testing using a sample collected in sodium citrate (to eliminate platelet clumping as a cause of spurious thrombocytopenia). She is diagnosed with abciximab-induced thrombocytopenia.

Heparin is stopped, and the patient receives 1 unit of single donor platelets with a prompt increase in her platelet count. She is continued on aspirin and clopidogrel and is started in a proton pump inhibitor. The platelet count begins to rise spontaneously on day 4 and returns to baseline levels within 1 week.

Comment

Severe thrombocytopenia (platelet count $<50 \times 10^9$/L) occurs in about 0.5% and less severe thrombocytopenia in 2% to 4% of patients treated with GP IIb/IIIa inhibitors.[22] Thrombocytopenia caused by GP IIb/IIIa inhibitors is readily distinguished from other causes by its rapid onset, typically within 24 hours of exposure and sometimes within with first hour, and severity (count often $<10 \times 10^9$/L). By contrast, heparin-induced thrombocytopenia is usually delayed until at least 4 days after starting heparin therapy (with the exception of patients with prior exposure to heparin in the past 3 months) and platelet counts rarely fall below 30×10^9/L. The very rapid onset of thrombocytopenia is believed to be caused by preformed antibodies that react with GP IIb/IIIa inhibitor–coated platelets. Spontaneous recovery of the platelet count usually occurs within days but can take several weeks. Patients with GP IIb/IIIa inhibitor–induced thrombocytopenia respond normally to platelet transfusions, which should be considered when the count is below 10×10^9/L to reduce the risk of spontaneous bleeding. There is no evidence that steroids or IV gamma globulin alter the natural history of GP IIb/IIIa inhibitor–induced thrombocytopenia. Repeated exposure to GP IIb/IIIa inhibitors should be avoided because there is a risk of recurrent thrombocytopenia, which may be more severe than the initial episode.

ANTICOAGULANT THERAPY

Anticoagulant therapy is effective for the initial and long-term management of patients with ACS with or without ST-segment elevation.[5,6,10] The pharmacologic characteristics of parenteral anticoagulants commonly used in the management of ACS are summarized in Table 148-5. Early trials suggested that heparin and aspirin were similarly effective for the prevention of MI, but aspirin was adopted as the foundation antithrombotic therapy because it caused less bleeding than heparin. Subsequent randomized controlled trials demonstrated that the combination of heparin plus aspirin provided additive benefit. More recent trials have established the efficacy and safety of newer parenteral anticoagulants, low-molecular-weight heparin (LMWH), fondaparinux, or bivalirudin, on a background of single- or dual-agent antiplatelet therapy in the initial management of patients with ACS.

The pharmacologic characteristics of warfarin and new oral anticoagulants evaluated in the management of ACS are summarized in Table 148-6.[23] Warfarin is effective for the prevention of major cardiovascular events for the long-term management of patients with ACS who are also treated with aspirin, but no adequately powered randomized controlled trials have evaluated the efficacy and safety of warfarin in the context of dual antiplatelet therapy. Two new oral anticoagulants (rivaroxaban and apixaban) have been evaluated in phase III trials for the long-term management of ACS, but neither agent is currently approved for this indication.[24,25]

Heparin

Heparin is derived from porcine intestinal mucosa and is administered by IV or subcutaneous injection. It inhibits coagulation by binding to antithrombin to produce a conformational change that converts antithrombin from a slow to a rapid inhibitor of thrombin and factor Xa.

Table 148-5 Pharmacologic Characteristics of Parenteral Anticoagulants Commonly Used in the Management of Patients With Acute Coronary Syndromes

	Unfractionated heparin	Enoxaparin	Bivalirudin	Fondaparinux
Route of administration	IV	SC (first dose IV*)	IV	SC (first dose IV*)
Frequency of dosing	Continuous IV infusion	Twice daily; once daily if CrCl <30 mL/min	Continuous IV infusion	Once-daily injection
Clearance	Primarily nonrenal	Renal	Renal, proteolytic cleavage	Renal
Use in ACS patients with moderate renal impairment	Yes	Yes (dose reduction)	Yes (dose reduction)	Yes[†]
Use in ACS patients undergoing dialysis	Yes	No experience	Yes (dose reduction)	No experience[‡]
Routine laboratory monitoring	Yes	No	No[§]	No
Dose	Adjust dose according to the results of the aPTT	Fixed weight adjusted	Fixed weight adjusted	Fixed
Accumulation in renal failure	No	Yes	Yes	Yes
Non-anticoagulant side effects	Allergy, HIT	HIT (rare)	—	—
Nonbleeding contraindications	Allergy, immune HIT	Allergy, immune HIT	Allergy	Allergy
Antidote	Protamine sulfate	No	No	No

ACS, acute coronary syndromes; *aPTT,* activated partial thromboplastin time; *CrCl,* creatinine clearance; *HIT,* heparin-induced thrombocytopenia; *IV,* intravenous; *SC,* subcutaneous.
*The first dose of enoxaparin was given by the intravenous route in the TIMI-11B (Thrombolysis In Myocardial Infarction 11B) and EXTRACT-TIMI 25 (Enoxaparin and Thrombolysis Reperfusion for Acute Myocardial Infarction Treatment, Thrombolysis in Myocardial Infarction 25) studies. The first dose of fondaparinux was given by the intravenous route in the OASIS-6 (Optimal Antiplatelet Strategy for InterventionS 6) trial.
[†]Acute coronary syndrome patients with creatinine up to 265 μmol/L were eligible for inclusion in the OASIS-5 and -6 trials (equivalent to an estimated creatinine clearance of 15 to 20 mL/min in a 70-kg patient who is 70 years of age).
[‡]Fondaparinux is contraindicated in patients with venous thromboembolism who have severe renal impairment.
[§]Monitoring and dose adjustment required in patients with creatinine clearance below 30 mL/min.

Table 148-6 Pharmacological Characteristics of Warfarin and New Oral Anticoagulants Evaluated in Phase 3 Trials for the Long-Term Management of Acute Coronary Syndromes

Characteristic	Warfarin	Rivaroxaban	Apixaban
Target	VKOR	fXa	fXa
Prodrug	No	No	No
Bioavailability, %	100	80	60
Dosing	Variable, once daily	Fixed, 2.5 or 5 mg twice daily*	Fixed, 5 mg twice daily (2.5 mg twice daily in selected patients)
Half-life	Mean, 40 hours (range, 20-60 hr)	7-11 hr	12 hr
Renal clearance, %	Nil	66[†]	25
Routine coagulation monitoring	Yes (INR)	No	No
Drug interactions	Multiple	Potent inhibitors of CYP3A4 and P-gp[‡]	Potent inhibitors of CYP3A4[‡]
Antidote	Yes (vitamin K, PCC, FFP)	No	No

CYP-3A4, Cytochrome p-450 3A4; *FFP,* fresh-frozen plasma; *fXa,* activated factor X; *INR,* international normalized ratio; *PCC,* prothrombin complex concentrates; *P-gp,* P-glycoprotein; *VKOR,* vitamin K epoxide reductase.
*A once-daily regimen was tested in atrial fibrillation.
[†]Half of renally cleared rivaroxaban is cleared as unchanged drug and half as inactive metabolites.
[‡]Potent inhibitors of both CYP3A4 and P-glycoprotein include azole antifungals (e.g., ketoconazole, itraconazole, voriconazole, posaconazole) and protease inhibitors, such as ritonavir. Potent inhibitors of CYP3A4 include azole antifungals, macrolide antibiotics (e.g., clarithromycin), and protease inhibitors (e.g., atanazavir).

Heparin has several limitations, including immune-mediated platelet activation, which leads to heparin-induced thrombocytopenia, and nonspecific protein binding, resulting in a variable anticoagulant response and the need for routine coagulation monitoring. Despite these limitations, heparin remains widely used because it has important advantages over more recently introduced anticoagulants. First, the anticoagulant effect of heparin can be rapidly and completely reversed with protamine sulfate. Second, heparin is suitable for use in patients with renal failure because it is predominantly nonrenally cleared. Third, unlike LMWH and fondaparinux, heparin is also highly effective for prevention of contact activation of coagulation induced by catheters and stents.[26]

Meta-analysis of four randomized controlled trials involving 1239 STEMI patients treated with aspirin and fibrinolytic therapy demonstrated that short-term IV heparin (given for about 1 week) compared with placebo or no heparin did not significantly reduce death or reinfarction but increased bleeding.[27] However, these trials were underpowered to demonstrate a benefit of heparin. Definitive data concerning the efficacy of heparin in STEMI patients treated with fibrinolysis come from a meta-analysis of 26 trials involving 73,000 patients, in which heparin, given either intravenously or subcutaneously, compared with placebo or no heparin reduced mortality and reinfarction.[28] Consistent benefits were evident in a subset of five trials in which patients also received aspirin; heparin compared with placebo or no heparin reduced both mortality (8.6% vs. 9.1%; $P = .03$) and reinfarction (3.0% vs. 3.3%; $P = .04$).

Short-term heparin therapy is also beneficial when added to aspirin in patients with NSTE ACS. A meta-analysis of six trials involving 1353 patients demonstrated that up to 7 days of IV heparin compared with placebo or no heparin reduced death or MI (4.5% vs. 7.4%; $P = .045$) with a nonsignificant excess of major bleeding.[29] Heparin has not been rigorously evaluated in ACS patients undergoing PCI but is routinely used in this setting.

Low-Molecular-Weight Heparin

Low-molecular-weight heparin is derived from heparin by enzymatic or chemical methods, yielding shorter polysaccharide chains that produce a more predictable anticoagulant effect than heparin and a lower propensity for thrombocytopenia. LMWH is given in fixed weight-adjusted doses without routine coagulation monitoring. The anticoagulant effects of LMWH can be partially reversed with protamine sulfate.

The CREATE trial ($n = 15,570$) was the largest of four trials that evaluated the efficacy and safety of various LMWH preparations in patients with STEMI also treated with aspirin and fibrinolysis.[30] Approximately half of patients in the CREATE trial were treated with dual antiplatelet therapy. The pooled data ($n = 16,943$) demonstrated that initial LMWH continued for up to 7 days compared with placebo reduced the risk of reinfarction (1.6% vs. 2.2%; $P < .05$) and death (7.8% vs. 8.7%; $P < .05$) at the cost of an increase in major bleeding (1.1% vs. 0.4%; $P < .05$).

Most of the trials comparing LMWH with heparin for the treatment of STEMI tested enoxaparin. Pooled data from eight trials involving 27,758 patients demonstrated that initial LMWH compared with heparin reduced the risk of MI (2.1% vs. 3.9%; $P < .05$) with similar rates of death (5.3% vs. 5.8%) at the cost of an increase in major bleeding (2.2% vs. 1.6%).[31] Consistent results were evident at 30 days.

The FRISC-1 (Fragmin during Instability in Coronary Artery Disease 1) trial evaluated the efficacy and safety of dalteparin in patients with NSTE ACS. Pooled data from FRISC-1 ($n = 1539$) and a second much smaller phase 2 study demonstrated that LMWH compared with placebo or no LMWH reduced the risk of MI or death (1.6% vs. 5.2%; $P < .0001$) with no significant increase in major bleeding.

Multiple trials have compared LMWH with heparin in patients with NSTE ACS. A pooled analysis of five trials involving 12,171 patients demonstrated that LMWH and heparin were associated with similar rates of MI or death (2.2% vs. 2.3%) and major bleeding.[29] A subsequent meta-analysis involving 21,946 patients with NSTE ACS demonstrated that enoxaparin compared with heparin reduced the risk of death or MI (10.1% vs. 11.0%; $P < .05$) with no increase in major bleeding.[32] The latter meta-analysis included some trials that did not involve the use of GP IIb/IIIa inhibitors and other trials in which they were widely used. The proportion of patients who underwent an invasive management strategy also varied among the trials.

Fondaparinux

Fondaparinux is a synthetic pentasaccharide that contains the essential five-sugar chain that interacts with antithrombin to inhibit factor Xa. Fondaparinux has a half-life of 17 hours, which enables once-daily administration and produces an even more predictable anticoagulant effect than LMWH and does not appear to cause thrombocytopenia. Fondaparinux does not have an antidote.

Fondaparinux has been evaluated in patients with ACS in three large phase 3 randomized controlled trials. The OASIS-6 trial evaluated fondaparinux in 12,092 STEMI patients treated with single or dual antiplatelet therapy and fibrinolytic therapy.[33] Fondaparinux (2.5 mg/day) compared with placebo or heparin reduced the risk of reinfarction or death (9.7% vs. 11.2%; $P = .008$) with consistent effects in patients with or without an indication for heparin therapy and in patients who received aspirin alone or the combination of aspirin and clopidogrel. Fondaparinux did not increase major bleeding. However, fondaparinux was associated with no benefit and a trend for harm in patients undergoing primary PCI.

The OASIS-5 trial evaluated fondaparinux in 20,078 patients with NSTE ACS treated with aspirin with or without clopidogrel. Fondaparinux (2.5 mg once daily) and enoxaparin (1 mg/kg twice a day) given for a mean of 6 days were associated with similar rates of the primary outcome of refractory ischemic, MI, or death at 9 days (5.8% vs. 5.7%), but there was a lower rate of major bleeding with fondaparinux (2.2% vs. 4.1%; $P < .001$).[34] At 30 days, fondaparinux compared with enoxaparin was associated with a reduced rate of death (2.9% vs. 3.5%; $P = .02$), which appeared to be explained primarily by the lower rate of bleeding. In 6238 invasively managed patients, fondaparinux and enoxaparin were associated with similar rates of the primary outcome but fondaparinux was associated with a small excess of catheter-related thrombosis (0.9% vs. 0.4%) and a reduction in major bleeding (2.4% vs. 5.1%; $P < .00001$). The risk of catheter thrombosis was largely prevented by the administration of heparin at the time of intervention.

The FUTURA OASIS-8 (Fondaparinux Trial With Unfractionated Heparin During Revascularization in Acute Coronary Syndromes) study evaluated the effect of standard dose heparin (85 units/kg bolus with additional boluses based on an activated clotting time dosing algorithm) compared with reduced dose heparin (50 units/kg without activated clotting time adjustment) on the primary composite outcome, bleeding or major vascular site access complications, in 2026 patients with NSTE ACS who were treated with fondaparinux and scheduled to undergo PCI within 72 hours.[35] The incidences of the primary outcome and of catheter-related thrombosis were similar in the two heparin dose groups, but death, MI, or target vessel revascularization occurred more often in the low-dose group. These data support the use of standard dose heparin in patients with NSTE ACS who are treated with fondaparinux and scheduled to undergo PCI.

Bivalirudin

Bivalirudin is an IV direct thrombin inhibitor that blocks the interaction between thrombin and its substrates. Bivalirudin has a short half-life of only 25 minutes after IV injection, making the lack of an antidote less problematic than for longer acting anticoagulants. It is about 20% renally cleared, and the half-life is prolonged in patients with renal impairment. Bivalirudin does not cause heparin-induced thrombocytopenia.

The efficacy and safety of direct thrombin inhibitors in ACS patients and those undergoing PCI was examined in the Direct Thrombin Inhibitor Trialists' Collaboration meta-analysis involving data from 11 trials and 35,970 patients.[36] The pooled data indicated a significant benefit of direct thrombin inhibitors (including bivalirudin) compared with heparin for the prevention of MI or death. Clopidogrel and GP IIb/IIIa inhibitors were not used in the trials included in this meta-analysis.

The HORIZONS AMI (Harmonizing Outcomes with Revascularization and Stents in Acute Myocardial Infarction) trial evaluated the use of bivalirudin in 3600 STEMI patients treated with the combination of aspirin and clopidogrel and undergoing PCI.[37] Bivalirudin plus provisional GP IIb/IIIa inhibitor compared with heparin plus GP IIb/IIIa were associated with similar rates of the primary outcome, MI, target vessel revascularization, stroke, or death (5.4% vs. 5.5%) at 30 days, but bivalirudin significantly reduced major bleeding (4.9 vs. 8.3%; $P < .0001$).

The ACUITY (Acute Catheterization and Urgent Intervention Triage Strategy) trial evaluated the use of bivalirudin in 13,819 patients with NSTE ACS undergoing PCI who were treated with the combination of aspirin plus clopidogrel as well as a GP IIb/IIIa inhibitor.[38] Bivalirudin was non-inferior to heparin or enoxaparin plus a GP IIb/IIIa inhibitor for the prevention of MI, unplanned revascularization, or death at 30 days (7.8% vs. 7.3%) but was associated with a lower rate of major bleeding (3.0% vs. 5.7%; $P < .001$).

Oral Anticoagulation

Warfarin is an oral vitamin K antagonist that has been evaluated in the long-term management of patients with ACS who are treated with aspirin but has not been rigorously tested on a background of dual antiplatelet therapy. Furthermore, the efficacy and safety of the combination of aspirin plus warfarin have not been compared with those of dual antiplatelet therapy.

The results from a meta-analysis of 14 trials involving 25,307 patients demonstrated that long-term warfarin (target INR, 2.0-3.0) compared with placebo or no warfarin reduced the risk of MI, ischemic stroke or death (9.4% vs. 12.3%; $P < 0.0001$) at the cost of a 2-fold increase in major bleeding (2.6% vs. 1.1%; $P < .00001$).[39]

Rivaroxaban and apixaban are orally active factor Xa inhibitors that have undergone evaluation in phase 3 trials for the long-term management of patients with ACS. The ATLAS TIMI-51 trial compared rivaroxaban (2.5 or 5 mg twice a day) with placebo in 15,526 ACS patients, the majority of whom were also treated with the combination of aspirin and clopidogrel.[24] Treatment was started a median of 4.7 days after onset of symptoms and was continued for a mean of 13 months. Rivaroxaban significantly reduced the risk of MI, stroke, or cardiovascular death (8.9% vs. 10.7%; $P = .008$) at the cost of an increase in non-CABG major bleeding (2.1% vs. 0.6%; $P < .001$) and intracranial bleeding (0.6% vs. 0.2%; $P = .009$). The APPRAISE trial compared apixaban (5 mg twice a day; 2.5 mg twice a day in selected patients) with placebo in patients with ACS. The trial was stopped early because of an excess of bleeding with no significant reduction in ischemic events.[25] The oral direct thrombin inhibitor dabigatran etexilate has been tested in a phase 2 trial but has not undergone evaluation in a phase 3 trial in ACS patients (see Table 148-7 and box on Case 4: Triple Therapy).

CONCLUSIONS AND FUTURE DIRECTIONS

Antiplatelet and anticoagulant drugs are effective for the prevention of MI and death across the spectrum of patients presenting with ACS, including STEMI patients treated with fibrinolytic therapy and those undergoing mechanical reperfusion. Aggressive antithrombotic treatment regimens involving multiple antiplatelet drugs given in combination with an anticoagulant during the acute phase have substantially reduced the risk of early and late recurrent ischemic events and stent thrombosis in ACS patients but at the cost of an increased risk of bleeding. Clinicians require detailed knowledge of the pharmacology and side effects profile of antithrombotic therapies used in the management of patients with ACS to optimize clinical outcomes. Comparative effectiveness studies are urgently required to further define those combinations of antithrombotic drugs that will maximize the net clinical benefit for patients with ACS by minimizing the risk of both thrombotic and bleeding events.

Table 148-7 Strategies Aimed at Minimizing the Risk of Bleeding in Patients Treated With Triple Therapy (Dual Antiplatelet Therapy and an Oral Anticoagulant)

Proposed Approach	Rationale
Aspirin maintenance dose ≤100 mg/day	Higher aspirin maintenance doses increase bleeding, and there is no evidence that they improve efficacy.
PPI with a preference for agents that interfere less with CYP 2C19 (e.g., pantoprazole)	Much of the excess bleeding is from the GI tract. The use of acid-suppressive agents that interfere less with CYP 2C19 minimizes the potential for a negative interaction with clopidogrel.
For warfarin, use a target INR of 2 to 2.5	Some evidence that a restricted target INR range reduces the risk of bleeding.
Manage warfarin in a specialized anticoagulation clinic	Compared with usual care, specialist clinics achieve a higher time-in-therapeutic-range of the INR.
Minimize duration of triple therapy	The risk of bleeding is highest during the first 30 days but remains elevated with long-term treatment.
Avoid NSAIDs	NSAIDs are a common cause of upper GI bleeding.
Avoid prasugrel and ticagrelor	Prasugrel and ticagrelor cannot be recommended because they are more potent and cause more bleeding than clopidogrel.

CYP, Cytochrome P450; *GI,* gastrointestinal; *INR,* international normalized ratio; *NSAID,* nonsteroidal antiinflammatory drug; *PPI,* proton pump inhibitor.

Case 4: Triple Therapy

A 55-year-old woman with a recent anterior MI treated who underwent primary PCI with implantation of a drug-eluting stent in the left anterior descending coronary artery is found to have a left ventricular thrombus on transthoracic echocardiogram. She is taking aspirin and clopidogrel. She is started on IV heparin, which is overlapped with warfarin until an INR of 2 is achieved. She is discharged home on triple antithrombotic therapy with aspirin, clopidogrel, and warfarin.

Comment

Anticoagulation is indicated for the management of left ventricular thrombosis, and the combination of aspirin and clopidogrel is indicated for the management of patients with drug-eluting stents. The combination of anticoagulation and dual antiplatelet therapy is associated with a 2% to 3% incidence of major bleeding during the first 30 days and a 4% to 12% incidence during the first year.[40] Strategies that may help to minimize the risk of bleeding in patients receiving triple antithrombotic are summarized in Table 148-7. The new oral anticoagulants dabigatran etexilate (110 mg twice a day) and apixaban (5 mg twice a day) may offer an advantage if they are used instead of warfarin in patients who require triple antithrombotic therapy because they cause less bleeding than warfarin in direct head-to-head comparisons.[41,42] However, all anticoagulants, including the new oral agents, increase the risk of bleeding when added to dual antiplatelet therapy.

CHAPTER 149

ATRIAL FIBRILLATION

Stavros Apostolakis and Gregory Y.H. Lip

Atrial fibrillation (AF) is a supraventricular arrhythmia characterized by uncoordinated atrial activation and loss of synchronous atrial mechanical activity. Typically, AF occurs in patients with underlying heart disease, such as hypertension or coronary or valvular heart disease; pulmonary pathology and thyroid disease; or other noncardiac causes. Nevertheless, a substantial proportion of patients with AF have no overt cardiovascular disease.

EPIDEMIOLOGY

AF is the most common sustained arrhythmia, affecting 5% of people older than 65 years. An analysis of the Framingham study indicates that the lifetime risk of developing AF from age 40 years onward is approximately 25% for the general population.[1] The estimated overall prevalence of AF is 0.9% in the United States and increases steadily to 3% to 5% in people older than 65 years and to 10% or higher in people older than 80 years of age. A similar prevalence has been reported in most regions of Western Europe.

The incidence of AF follows a similar pattern and also has a propensity to increase with age. The Framingham study, over a 38-year follow-up period, found an overall incidence of three in 1000 person-years in men and two in 1000 person-years in women ages 55 to 64 years.[1,2] The Manitoba follow-up study in Canada reported a similar overall incidence rate of two in 1000 person-years. The incidence of AF increases exponentially with advancing age to 20 to 30 per 1000 patient-years in individuals 85 years of age and older.[3]

AF is 1.5 times more common in men than in women. Moreover, the onset of AF in women occurs at a later age than in men (mean age, 65 years versus 60 years). Interestingly, the incidence pattern of AF shows racial and geographical variations.[2] The Cardiovascular Health Study reported that incidence of AF among white subjects was twice that among African Americans. The incidence and prevalence of AF appear to be similar in the United States and Western Europe but possibly lower in Asia.

Projected data from population-based studies, such as the ATRIA (Anticoagulation and Risk Factors in Atrial Fibrillation) study in California and analysis from the Mayo Clinic in Olmsted County, Minnesota, suggest that the number of adults with AF may reach 5.6 to 12.1 million by 2050. In fact, this number could be as high as 15.9 million if a continuous rise in the incidence of AF is present.

PATHOPHYSIOLOGY: A BRIEF OVERVIEW

Genesis and Preservation of Atrial Fibrillation

The pathophysiology of AF includes triggers that provoke the arrhythmia and a variety of electromechanical phenomena that sustain it. The triggers are diverse, and it is unclear whether they can induce AF in the absence of other contributors.[4] Triggers include sympathetic or parasympathetic stimulation, bradycardia or tachycardia, and atrial premature beats and acute atrial stretch. Ectopic foci occurring in areas of atrial tissue within the pulmonary veins or vena caval junctions have also been considered triggers of the arrhythmia.[5] When triggered, AF may be brief; however, a variety of factors may act as perpetuators to promote the persistence of AF. One is persistence of trigger factors and initiators that induce AF; nevertheless, AF often persists in their absence. This is probably the result of electrical and structural remodeling, characterized by atrial dilatation and shortening of the atrial effective refractory period. The longer AF persists, the more difficult it is to restore and maintain sinus rhythm. Early cardioversion progressively reduces the total time that patients are in AF and progressively increases the time between recurrences. The latter observation is attributed to the prevention of long-lasting AF paroxysms and subsequently to the prevention of electrophysiological remodeling.

Advanced age is also a perpetuating factor for AF with an obscure pathophysiological background. Age and atrial disease are associated with increases in connective tissue degeneration and atrial scarring. Fibrotic myocardium exhibits slow conduction; thus, reentrant circuits—only a few millimeters in diameter—can develop in discontinuously conducting tissue. Atrial regions with advanced fibrosis can be local "sources" for AF.

Thrombosis and Embolism

Thromboembolic events related to AF result in significant morbidity and mortality. Thrombi have a predilection to form within the left atrial appendage (LAA) in patients with AF (Fig. 149-1). Approximately 90% of atrial thrombi in nonvalvular AF and 60% of thrombi in patients with mitral valve disease are formed within the LAA. The LAA is a long, tubular, hooked structure that is usually crenulated and has a narrow junction with the main atrial cavity. The LAA is the remnant of the original embryonic left atrium that develops during the third week of gestation. The main smooth-walled cavity of the left atrium develops later and is formed from the outgrowth of the pulmonary veins.[6]

In sinus rhythm, the LAA contracts to a greater extent than the rest of the left atrium and has a distinct pattern of contraction. Blood flow within the LAA has been studied with transesophageal echocardiography (TEE), which provides better views of the appendage and its orifice than transthoracic echocardiography (TTE). Doppler-measured LAA flow in patients with sinus rhythm was initially described as biphasic, but additional emptying and filling waves resulting in quadriphasic appendage flow have been described in 40% to 70% of patients.[6]

Thrombus formation in AF is consistent with the fulfillment of the Virchow triad of thrombogenesis, with intraatrial stasis, endothelial dysfunction, and a prothrombotic or hypercoagulable state. Reduced or absent LAA inflow and outflow velocities and low LAA ejection fractions are commonly observed in patients in AF (Fig. 149-2). Mechanical dysfunction leads to blood stasis and thrombus formation. The cause of LAA dysfunction, however, has not been fully elucidated. It is likely to be related in part to a myopathic process that results in AF or that occurs as a result of the AF itself. Endothelial dysfunction has also been recognized as a contributor to thrombus formation in AF, and along with stasis, contributes to a

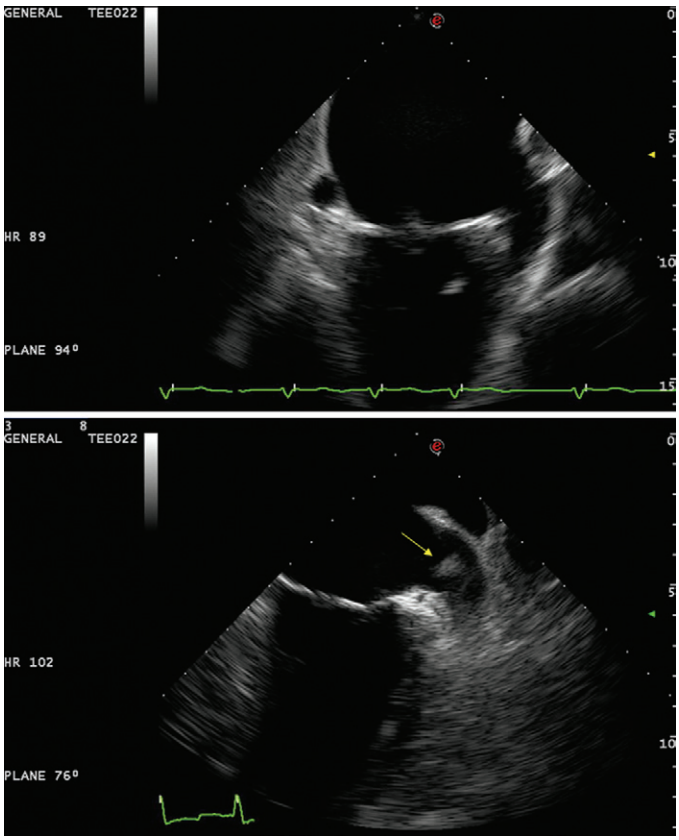

Figure 149-1 TRANSESOPHAGEAL VIEWS OF LEFT ATRIAL APPENDAGE (LAA). The LAA is a long, tubular, hooked structure that is usually crenulated and has a narrow junction with the venous component of the atrium. Thrombi have a predilection to form within the LAA *(yellow arrow)*.

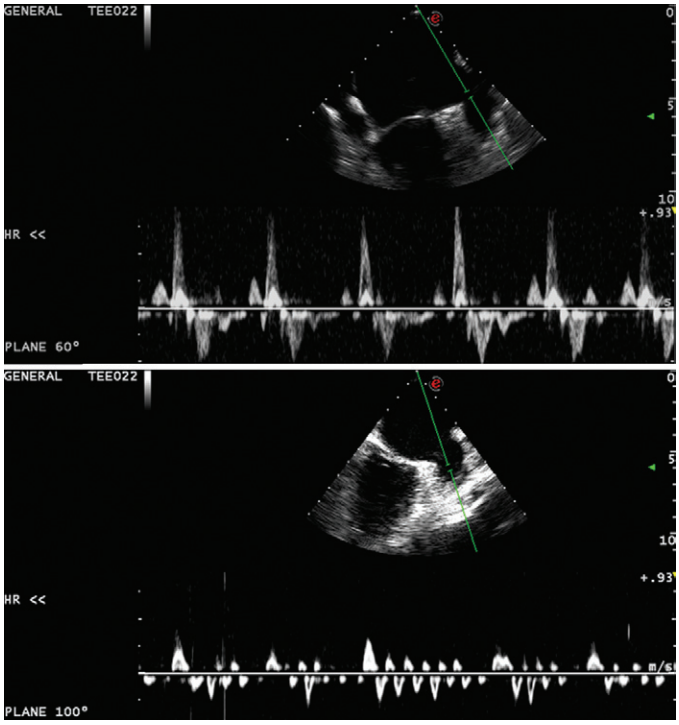

Figure 149-2 DOPPLER MEASURED LEFT ATRIAL APPENDAGE (LAA) FLOW IN A PATIENT WITH SINUS RHYTHM *(UPPER)*. Reduced LAA inflow and outflow velocities are observed in patients in atrial fibrillation.

hypercoagulable state. Elevated plasma and atrial tissue levels of prothrombotic markers, such as D-dimer, P-selectin, and von Willebrand factor, have been reported in patients with AF independent of associated comorbidities or structural heart disease, leading to the concept that AF induces a systemic hypercoagulable state.

The size and mobility of the LAA thrombus are other determinants of thromboembolic risk. Mobile thrombi with a diameter greater than 15 mm have been associated with an increased risk of thromboembolism.[6]

Functional indices of LAA stasis are restored after conversion to sinus rhythm. However, patients with AF who are successfully cardioverted with drugs or DC shock show depressed AF mechanical function for a variable period after restoration of sinus rhythm. These findings support the concept that such patients require antithrombotic therapy for at least 4 weeks after successful cardioversion.

CLINICAL MANIFESTATION AND DIAGNOSIS

History and Physical Examination

AF is often asymptomatic, and it is not unusual for a patient to first become aware of AF during a routine physical examination. When symptoms occur, they are commonly associated with rapid ventricular rate. Rapid and irregular heart rates may be experienced as palpitations, exercise intolerance, or vague chest discomfort. In some patients with persistently elevated ventricular rates, cardiomyopathy may occur, leading to heart failure as the prominent manifestation of AF. Syncope is a rare complication of AF that can occur in patients with sinus node dysfunction, with rapid ventricular rates in patients with left ventricular outflow obstruction, or when an accessory pathway exists. It is not uncommon for patients with AF to present with an acute ischemic stroke, transient ischemic attack (TIA), or systemic embolism (see Chapter 147).[7]

Common findings suggestive of AF during physical examination are an irregular pulse, variation in the intensity of the first heart sound, or absence of a previously heard fourth heart sound. Examination may also reveal associated valvular heart disease, myocardial abnormalities, or heart failure. A pulse deficit may be present if the left ventricular stroke volume is insufficient to produce a palpable peripheral pressure wave with rapid ventricular rates.

Because most cases of AF are secondary to other medical conditions, a detailed medical history is important to assess the presence of angina, hyperthyroidism, or lung disease. A previous history of stroke or TIA, as well as hypertension, diabetes, heart failure, and rheumatic fever, may indicate whether a patient is at a higher risk of thromboembolism.[7]

Additional Testing and Cardiac Imaging

The diagnosis of AF is based on a detailed history and clinical examination, and electrocardiographic (ECG) recordings confirm the arrhythmia. The initial evaluation of a patient with suspected or documented AF involves defining the pattern of the arrhythmia, identifying its cause, and revealing associated cardiac and noncardiac factors relevant to the etiology.

Electrocardiography is the gold standard for the diagnosis of AF. A single-lead recording during the arrhythmia is sufficient to establish the diagnosis. Diagnostic ECG criteria include absence of P waves, irregular timing, fibrillatory (F) waves between QRS complexes, and irregularly irregular R-R intervals (Fig. 149-3).

Echocardiography and thyroid function tests are important in the initial evaluation. A chest radiograph may detect enlargement of the cardiac chambers and heart failure; however, it is less important than echocardiography for routine evaluation of patients with AF. As part of the initial evaluation, all patients with AF should undergo two-dimensional and Doppler echocardiography to assess left atrial and left ventricular dimensions and function and to reveal underlying

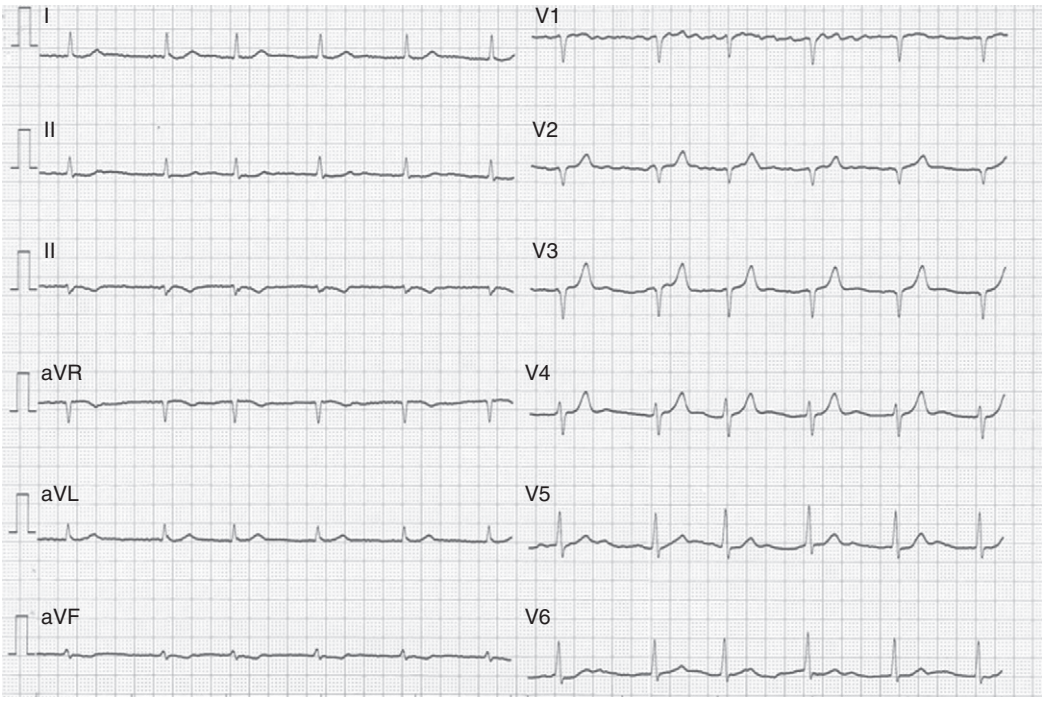

Figure 149-3 TYPICAL 12-LEAD ELECTROCARDIOGRAM OF ATRIAL FIBRILLATION. Absence of P waves, irregular timing, and morphology fibrillatory (F) waves and irregularly irregular R-R intervals are evident.

structural heart disease. Quantification of left ventricular systolic function further assists decision making regarding antiarrhythmic and antithrombotic therapy.[7]

Blood tests are important in initial assessment but can be limited to tests of thyroid, renal, and hepatic function, serum electrolytes, and a hemogram. These tests should be performed at least once in the course of the patient's evaluation. Novel markers of cardiovascular disease have been assessed in AF, but their prognostic and diagnostic impact remains obscure. Natriuretic peptides have been found to be elevated in patients with paroxysmal and persistent AF and decline rapidly after sinus rhythm is restored. Although high levels of B-type natriuretic peptide have been associated with thromboembolism and recurrences of AF, further studies are needed to evaluate their prognostic significance.

Prolonged ECG monitoring may be necessary to reveal episodes of asymptomatic AF. Ambulatory ECG monitoring may also document the adequacy of rate control and further guide therapy. Exercise testing is recommended when myocardial ischemia is suspected before the initiation of type Ic antiarrhythmic agents and when the adequacy of rate control on activity needs to be assessed.

Transesophageal echocardiography is the most sensitive and specific technique to detect sources of cardiogenic embolism and has been most effectively used to stratify stroke risk in patients with AF scheduled for cardioversion. However, TEE is not recommended as part of the routine initial evaluation of patients with AF. Contrast-enhanced magnetic resonance imaging is a promising technique for the detection of intracardiac thrombi with a reported sensitivity higher than TTE and comparable to TEE. Finally, an electrophysiological study can be useful in cases in which AF is a consequence of reentrant tachycardia such as atrial flutter, intraatrial reentry, or atrioventricular (AV) reentry involving an accessory pathway.

Differential Diagnosis

Other irregular rhythms may resemble AF on ECG, but these can easily be distinguished by the presence of discrete P waves. Atrial flutter, in the typical form, is characterized by a saw-tooth pattern of regular atrial activation, called flutter (F) waves on the ECG, which is particularly visible in leads II, III, aVF, and V1, especially with vagal maneuvers. With atrial flutter, the atrial rate typically ranges from 240 to 320 stimuli per minute. Atrial flutter commonly occurs with 2:1 AV block, resulting in a regular or irregular ventricular rate of approximately 150 beats/min.

In most other atrial tachycardias, P waves can readily be identified in one or more ECG leads. The morphology and the arrangement of the P waves relative to the preceding and the forthcoming QRS complexes may help identify the origin of the tachycardia.[7]

Prognosis

AF is clinically relevant. It may indicate underlying heart disease or cause symptoms related to hemodynamic impairment or palpitations. However, the most important reason to make the diagnosis of AF is because of the increased risk of stroke and systemic thromboembolism. On average, the overall risk of stroke among individuals with AF is about 5% per year and is about five or six times greater than the risk among age-matched subjects in sinus rhythm.

AF is also an accurate marker of future morbidity. Large-scale studies have demonstrated increased risk of all-cause mortality and death from cardiovascular causes in AF patients, ranging from a 1.3- to 1.8-fold increase for men and 1.9- to 2.8-fold increase for women. AF imposes a substantial cost burden on the health care system because of the increased arrhythmia-related morbidity and mortality and the significant cost associated with management strategies.[7]

AF can occur after acute myocardial infarction or cardiac surgery, and it can be found in association with pericarditis, myocarditis, hyperthyroidism or acute pulmonary disease. In these settings, AF is not the culprit condition, and treatment of the underlying disorder usually terminates the arrhythmia and diminishes the chance of recurrences. The term *lone AF* has been generally applied to young individuals without evidence of cardiovascular disease. These patients have a favorable prognosis regarding both thromboembolism and mortality.

THERAPY

General Considerations

There are two ways to approach arrhythmia-related symptoms in patients with AF: rate control and rhythm control. Whereas rhythm control strategies aim to restore and maintain sinus rhythm, rate control uses interventions to maintain the heart rate within normal range with no commitment to restoring sinus rhythm. The wide heterogeneity in both the clinical presentation and the clinical background of AF necessitates a personalized approach to its management. Such an approach requires selection of the appropriate rhythm control or rate control strategy, taking into account the impact of each strategy on prognosis, quality of life, and financial resource utilization. In general, antiarrhythmic drugs and invasive procedures have proven to be effective for rate and rhythm control, and for selected patients, intervention may be the preferred option. Regardless of the initial approach, the need for anticoagulation is based on individualized stroke risk and not on whether sinus rhythm is restored and maintained. For rhythm control, drugs are typically the first choice. However, in young symptomatic patients, radiofrequency ablation may be preferable to long-term drug therapy. Few patients are candidates for a stand-alone surgical procedure to cure AF using the Cox-maze procedure or left atrial ablation techniques; however, these approaches can be valuable additions to coronary bypass or valve repair surgery to prevent recurrences of AF.

Rhythm or Rate Control

Prophylactic antiarrhythmic drug therapy should ideally maintain sinus rhythm, minimize symptoms, improve exercise capacity, and prevent tachycardia-induced cardiomyopathy. Nevertheless, maintenance of sinus rhythm does not seem to prevent thromboembolism or heart failure or reduce mortality. Trials comparing rate versus rhythm control approaches in patients with persistent or paroxysmal AF concluded that rhythm control offered no benefits in terms of reduction in death, disabling stroke, hospitalizations, new arrhythmias, or thromboembolic complications. The AFFIRM (Atrial Fibrillation Follow-up Investigation of Rhythm Management) trial, which randomized 4060 patients to either strategy, demonstrated no difference in mortality or stroke rate with rhythm versus rate control.[8] Similarly, the RACE (Rate Control versus Electrical cardioversion for persistent atrial fibrillation) trial recruited 522 patients and concluded that rate control is noninferior to rhythm control for prevention of death and morbidity.[9] Therefore, pharmacologic therapy to maintain sinus rhythm should only be considered in symptomatic patients who can tolerate antiarrhythmic drugs and have a high probability of retaining sinus rhythm for an extended period. Physicians should not insist on antiarrhythmic medication when it does not improve symptoms or is poorly tolerated.

Direct current cardioversion is the most effective method for restoring sinus rhythm. However, whether cardioversion by electrical shock has advantages over medical cardioversion has never been subjected to a randomized clinical trial.

General Approaches to Pharmacologic Antiarrhythmic Therapy

As an initial approach, every reversible precipitant of AF should be corrected before the administration of any antiarrhythmic agent. Indefinite antiarrhythmic treatment is usually not recommended after a first episode of AF. Selection of an appropriate agent is based on safety, tolerability, the underlying cardiovascular pathology, and the individual characteristics of AF. A drug that is initially safe may become proarrhythmic if coronary disease or heart failure develops or if the patient begins other potentially proarrhythmic medication. Consequently, patients should be regularly reassessed and informed about the potential significance of symptoms suggestive of rhythm disorders.

There is general agreement between the European and the North American cardiovascular societies on the antiarrhythmic management of AF. According to the latest consensus documents, β-adrenergic antagonists may be effective in patients who only develop AF during exercise. Likewise, in patients with lone AF, a β-blocker may be initially recommended, although flecainide, propafenone, and sotalol are particularly effective for rhythm maintenance. Amiodarone may also be instituted for chronic treatment when conventional measures are ineffective, but it may cause severe extracardiac adverse events, including thyroid dysfunction and bradycardia. Dronedarone has a better long-term safety profile than amiodarone and according to the latest guidelines should be considered before amiodarone for rhythm maintenance in patients with acute coronary syndromes, chronic stable angina, hypertensive heart disease, and stable New York Heart Association class I to II heart failure. Quinidine, procainamide, and disopyramide are not favored unless amiodarone is ineffective or contraindicated. In patients in whom treatment with a single antiarrhythmic agent fails, combination therapy may be considered. Effective combinations include a β-blocker, such as sotalol, or amiodarone with a class Ic agent. The addition of a calcium channel blocker, such as diltiazem, to a class Ic agent, such as flecainide or propafenone, is also beneficial for some patients, especially to avoid 1:1 atrial flutter with the class I agent.[10]

The safety of dronedarone has been questioned lately based on data derived both from postmarketing surveillance and clinical trials. In the PALLAS (Permanent Atrial fibriLLAtion Study) trial, dronedarone increased rates of heart failure, stroke, and death from cardiovascular causes in patients with permanent AF who were at risk for major vascular events.[10] The PALLAS investigators concluded that this drug should not be used in such patients. Moreover, the Food and Drug Administration (FDA) has received several case reports of hepatocellular liver injury and hepatic failure in patients treated with dronedarone, including two postmarketing reports of acute hepatic failure requiring transplantation.

Pharmacologic management to achieve rate control in AF patients should be tailored to the potential concomitant cardiac disease states, particularly coronary artery disease or heart failure. β-Blockers may be especially useful when high adrenergic tone or symptomatic myocardial ischemia occurs in association with AF. Nondihydropyridine calcium channel antagonists (i.e., verapamil or diltiazem) are particularly effective for acute and chronic rate control in AF; however, these drugs are contraindicated in patients with systolic dysfunction because of their negative inotropic effect. Digoxin is effective for control of heart rate at rest but not during exercise, but it may be effective in combination with a β-blocker in patients with heart failure. Digoxin may cause adverse effects in patients with heart failure and can interact with other drugs. Amiodarone is an effective rate control drug even though it is often started for rhythm control. Class I antiarrhythmic drugs are not effective for rate control.[10]

The optimum way for monitoring antiarrhythmic therapy varies depending on the agent and the patient's cardiovascular comorbidities. In patients given class Ic agents, prolongation of the QRS interval should not exceed 50%. Exercise testing may help to detect QRS widening that occurs only with rapid heart rates. In patients treated with class IA or class III drugs, with the possible exception of amiodarone, the corrected QT interval in sinus rhythm should be kept below 520 msec. During follow-up, plasma potassium and magnesium levels and renal function should be checked periodically.[10]

Nonpharmacologic Approaches

The limited efficacy and potential toxicity of antiarrhythmic drugs have lead to the exploration of alternative, nonpharmacologic strategies for the management of AF.

The Cox-maze procedure was developed by James Cox and associates and was first performed at St. Louis' Barnes Hospital in 1987.[11]

This surgical approach creates conduction barriers within the atria and reduces the mass of the left and right atrium to prevent or block the microreentry circuits that maintain the arrhythmia. From the technical standpoint, the procedure involves encircling the pulmonary veins with multiple linear incisions over both atria using either the cut-and-sew technique or different energy probes. The success rate of the procedure ranges from 85% to 95%. Moreover, removal or closure of the LAA together with maintenance of sinus rhythm reduces the long-term stroke rate to less than 1%. However, the procedure is invasive. Recent modifications use minimally invasive thoracoscopic techniques and different energy ablation probes to shorten the procedure time and improve safety.

Device Therapies—Atrial Pacing and Defibrillation

There is no evidence to support the use of permanent atrial pacing to treat paroxysmal AF in patients without a conventional indication for pacing. However, in patients with sinus node disease, symptomatic bradycardia, or chronotropic incompetence in need of permanent pacing, the use of dual-chamber or atrial pacemakers reduces the occurrence of AF. Although many modern pacemakers and implantable ventricular defibrillators have features such as overdrive pacing, antitachycardia atrial pacing, and atrial defibrillation that are designed to prevent or terminate AF, data from large randomized trials do not support their routine use.[10,12]

Catheter Ablation

Ablation of the AV node and permanent pacing is an effective method for rate control and symptomatic relief in patients with antiarrhythmic drug-resistant AF and for those who cannot tolerate drug therapy. A meta-analysis, involving 1181 patients, reported significant improvement in quality-of-life and clinical outcome measures after ablation and pacing therapy with acceptable 1-year total and sudden death mortality rates. However, this approach leads to pacemaker dependency, a requirement for indefinite anticoagulation, and is associated with proarrhythmia.

Catheter ablation strategies to treat AF aim to eliminate the triggers that initiate or promote the arrhythmia and to modify the electrophysiological background that sustains it. In patients with paroxysmal AF, arrhythmogenic foci in the pulmonary veins, or less commonly from other atrial sites, may be important triggers of the disease and subsequently therapeutic targets. Isolation of these arrhythmogenic sites can eliminate recurrences in 80% to 90% of the treated patients.[13,14] Different catheter ablation techniques are used to electrically isolate the pulmonary veins from the left atrium or to modify the left atrial tissue around the pulmonary veins (circumferential ablation). The safety and efficacy of pulmonary vein isolation has been compared with antiarrhythmic drug therapy in a few randomized trials with promising results. However, catheter ablation procedures are technically challenging and operator dependent. This is reflected in the inconsistent rates of success and adverse events in clinical trials and in clinical practice. In addition, the long-term effectiveness of catheter ablation procedures remains obscure. Development of new catheter ablation techniques and the use of different imaging and navigation systems may improve the success and safety of the procedure.

PREVENTION OF THROMBOEMBOLISM

Cardioversion and Thromboembolism Prevention

Patients who have been in AF for more than 48 hours—or those in whom the onset of the arrhythmia cannot be accurately defined—may be considered for anticoagulation therapy and strategies to restore and maintain sinus rhythm. Adjusted-dose warfarin within the therapeutic range should be administered for 3 weeks before cardioversion is attempted. If cardioversion cannot be postponed, a TEE should be performed. Cardioversion can be undertaken with an acceptable risk of stroke if TEE excludes LAA thrombus.[15] However, if TEE identifies LAA thrombus, cardioversion should be delayed until the patient has been anticoagulated for at least 3 to 4 weeks and a repeat TEE reveals thrombus dissolution. If the thrombus persists, cardioversion should not be performed.

After successful cardioversion, warfarin therapy should be continued for at least 4 weeks to prevent thrombus formation in the "stunned" left atrium. If the patient has a low risk of recurrent AF and remains in sinus rhythm for 1 month after cardioversion, anticoagulation therapy with warfarin can be stopped. In patients at higher risk of thromboembolism, it may be more appropriate to continue warfarin therapy indefinitely.[10,12]

Long-Term Primary and Secondary Prevention of Thromboembolism

Risk Stratification

Patients with AF have a substantial risk of stroke and systemic thromboembolism compared with age-matched people in sinus rhythm. This risk depends on comorbidities and demographic factors and ranges from less than 1% to more than 20% per year.[16] The important independent prognostic factors for an increased risk of AF-related stroke are increasing age, a history of previous TIA or stroke, hypertension, diabetes mellitus, and evidence of moderate to severe left ventricular systolic dysfunction. Echocardiographic evidence of left atrial enlargement and left atrial spontaneous echo contrast have also been associated with increased risk for AF-related stroke.[17] Moreover, these risk factors are cumulative: for people younger than 65 years old with no risk factors, the annual risk of stroke is about 1%. For the same age group, the untreated risk exceeds 12% if multiple risk factors are present. The complexity of the factors that influence thromboembolic risk in patients with AF necessitated the development of risk stratification schemas to identify the subgroup of patients who will benefit from anticoagulation.

The most widely used stroke risk classification scheme, known as $CHADS_2$ (Table 149-1 defines $CHADS_2$), was developed in 2001 and adapted by the American College of Cardiology/American Heart Association/European Society of Cardiology (ACC/AHA/ESC) guideline committee in 2006.[7] The $CHADS_2$ score classifies patients with 0 points as low risk, 1 point as moderate risk, and 2 points or more as high risk. Such a practice translates to better outcomes in AF patients because there is a clear relationship between $CHADS_2$ score and stroke rate.

In 2008, the Stroke in AF Working Group compared the predictive value of 12 published risk-stratification schemes, including the $CHADS_2$ score. The investigators concluded that most of these clinical tools had very modest predictive value for stroke, especially if patients were artificially categorized into low-, moderate-, and high-risk strata. The $CHADS_2$ score categorized most subjects as "moderate risk" and had a low c-statistic to predict stroke. Moreover, the $CHADS_2$ score did not include several stroke risk factors that have been substantiated in randomized studies and registries.[12]

The CHA_2DS_2-VASc scoring system was developed to overcome these problems (see Table 149-1). In this system, the "major" risk factors are defined as prior stroke, TIA, or systemic thromboembolism and older age (75 years or older). The presence of mitral stenosis or prosthetic heart valves also identifies AF patients as high risk. Clinically relevant nonmajor risk factors include heart failure—particularly moderate to severe systolic LV dysfunction—hypertension, or diabetes. Other clinically relevant nonmajor risk factors include female sex, age 65 to 74 years; vascular disease defined as myocardial infarction; and complex aortic plaque or peripheral arterial disease. That risk factors are still cumulative, and the simultaneous presence of two or more clinically relevant nonmajor risk factors justifies anticoagulation.

The ESC guidelines recommend the use of both $CHADS_2$ and CHA_2DS_2-VASc score. The $CHADS_2$ stroke risk stratification scheme

Table 149-1 CHA_2DS_2-VASc and $CHADS_2$ Scores*

CHA_2DS_2-VASc Score		$CHADS_2$ Score	
Major Risk Factors	**Points**	**Risk Factors**	**Points**
Previous stroke, TIA, or systemic embolism	2	Congestive heart failure or LV dysfunction	1
Age >75 years	2	Hypertension	1
Clinically Relevant Nonmajor Risk Factors		Age >75 years	1
Congestive heart failure or left ventricular dysfunction*	1	Diabetes mellitus	1
Hypertension	1	Previous stroke, TIA, or systemic embolism	2
Diabetes mellitus	1		
Vascular disease†	1		
Age 65-74 years	1		
Sex category (i.e., female sex)	1		
Maximum points	9		6

LV, Left ventricular; *TIA,* transient ischemic attack;
*Especially moderate to severe systolic LV dysfunction, defined arbitrarily as LV ejection fraction of 40% or less.
†Defined as myocardial infarction, complex aortic plaque, or peripheral arterial disease (PAD), including prior revascularization, amputation because of PAD, or angiographic evidence of PAD.

Table 149-2 The HAS-BLED score

	Clinical Characteristic	Point
H	Hypertension*	1
A	Abnormal renal† and liver function‡ (1 point each)	1 or 2
S	Stroke	1
B	Bleeding§	1
L	Labile INRs¶	1
E	Elderly (e.g., age >65 years)	1
D	Drugs¶ or alcohol (1 point each)	1 or 2
	Maximum points	9

*Systolic blood pressure >160 mm Hg.
†The presence of chronic dialysis or renal transplantation or serum creatinine ≥200 mmol/L.
‡Chronic hepatic disease (e.g., cirrhosis) or biochemical evidence of significant hepatic derangement.
§Previous bleeding history or predisposition to bleeding.
¶Unstable or high international normalized ratio (INR) or poor time in the therapeutic range.
¶Concomitant use of drugs, such as antiplatelet agents or nonsteroidal antiinflammatory drugs.

should be used as a simple initial means of assessing stroke risk, particularly suited to primary care physicians and nonspecialists. In patients with a $CHADS_2$ score of 2 or greater, chronic oral anticoagulation therapy should be prescribed unless contraindicated. In patients with a $CHADS_2$ score of 0 to 1 or when a more detailed stroke risk assessment is indicated, the CHA_2DS_2-VASc score can be used. A pragmatic view is also recommended in the guideline for certain patient groups. For example, in women ages 65 years with no other risk factors and normal echocardiography, aspirin (or no antithrombotic therapy) rather than oral anticoagulation therapy may be considered.

Risk factors predisposing to anticoagulant-associated hemorrhage have also been identified. These include previous symptomatic cerebrovascular disease; computed tomography scan evidence of small vessel disease; poorly controlled hypertension; and excessive anticoagulation, including factors predisposing to it, such as confusion, dementia, inadequate monitoring, and alcoholic liver disease. Increasing age predisposes to all of these risk factors; thus, it is considered a potent risk factor for anticoagulant-associated hemorrhage.[7]

In the latest edition of the ESC guidelines, a simple and user-friendly clinical tool was developed to assess 1-year risk of major bleeding in patients with AF based on analysis of data from 3978 participants of the EuroHeart Survey. The clinical tool was given the acronym HAS-BLED and includes most of the clinical predictors that have been associated with hemorrhagic complications related to antithrombotic therapy (Table 149-2). A score of 3 or greater indicates high risk. Regular patient review and HAS-BLED score calculation are needed to balance the risk of bleeding with the benefits of anticoagulant therapy.[12]

Warfarin for Stroke Prevention in Atrial Fibrillation

Strategies for reducing the risk of stroke and systemic thromboembolism in patients with chronic AF have been studied in many randomized controlled trials over the previous decades. Five large randomized primary prevention trials have shown that in people with chronic nonvalvular AF, warfarin reduces the overall risk of stroke from 4.5% to 1.4% per year with an acceptable increase in major bleeding rates. This translates to 30 strokes prevented per 1000 patient-years of treatment at a cost of at least two serious bleeds per 1000 patients per year.[18-22]

For secondary prevention, the European Atrial Fibrillation Trial investigators randomized 1007 patients with a recent TIA or minor ischemic stroke to open anticoagulation or double-blind treatment with either aspirin or placebo.[23] The authors concluded that in patients with chronic nonvalvular AF and a history of stroke or TIA, the annual risk of stroke is reduced from 12% to 4% with warfarin. The annual incidence of major bleedings was 2.8% in the anticoagulant group and 0.7% in the placebo group. Thus, in the secondary prevention setting, warfarin prevents 80 strokes per 1000 patient-years, at a cost of at least 20 major bleeds per 1000 patients treated for one year.

The optimal time to initiate anticoagulation therapy after a recent cerebrovascular accident depends on the risk of recurrent thromboembolism and the risk of hemorrhagic transformation of the infarct. Two randomized trials have demonstrated no benefit from early anticoagulation because any net gain obtained from reduction in recurrent ischemic stroke was offset by the excess hazard of hemorrhagic stroke. Thus, in the absence of evidence, common practice is to begin warfarin 3 to 14 days after patients present with an acute stroke (see Chapter 147).[7]

New Oral Anticoagulants for Stroke Prevention in Atrial Fibrillation

Dabigatran etexilate is an oral prodrug that is rapidly converted by a serum esterase to dabigatran, a potent, direct inhibitor of thrombin (see Chapter 151). In the RE-LY (Randomized Evaluation of Long Term Anticoagulant Therapy) study, 18,113 patients with AF and a risk of stroke were randomly assigned to fixed doses of 110 mg or 150 mg dabigatran twice daily or adjusted-dose warfarin. The primary outcome was stroke or systemic embolism. The results based on the criterion of noninferiority indicated that the dose of 150 mg twice a day was significantly more effective than warfarin in the prevention of ischemic stroke with similar rates of major hemorrhage. The dose of 110 mg twice a day was similar to warfarin in the prevention of thromboembolism and was associated with significantly lower rates of hemorrhagic events.[24]

Rivaroxaban is the first available orally active direct factor Xa inhibitor (see Chapter 151). It possesses impressive pharmacologic properties, including once-daily oral administration, rapid onset of action, and predictable pharmacokinetics. The ROCKET-AF (Rivaroxaban Once-daily oral direct factor Xa inhibition Compared with vitamin K antagonism for prevention of stroke and Embolism Trial in Atrial Fibrillation) recruited 14,264 patients with nonvalvular AF at increased risk for stroke. Patients were randomly assigned to receive either rivaroxaban at a daily dose of 20 mg or dose-adjusted warfarin. The investigators concluded that in patients with AF, rivaroxaban was noninferior to warfarin for the prevention of stroke or systemic embolism. Moreover, there was no significant between-group difference in the risk of major bleeding. Nevertheless, intracranial and fatal bleeding occurred less frequently in the rivaroxaban group.[25]

Apixaban is the second direct inhibitor of activated factor X that completed successfully phase III trials (see Chapter 151). The AVERROES (Apixaban versus Acetylsalicylic Acid to Prevent Strokes) trial was a double-blind study that recruited 5599 patients with AF who were at increased risk for stroke and for whom vitamin K antagonist (VKA) therapy was considered unsuitable. The study participants were randomly assigned to receive either 5 mg of apixaban twice daily or aspirin. The primary outcome was stroke or systemic embolism. Treatment with apixaban was associated with a 55% reduction in the risk of stroke or systemic embolism compared with aspirin. The risk of major bleeding was not significantly different between apixaban and aspirin.[26] In the ARISTOTLE (Apixaban for Reduction In Stroke and other ThromboembolLic Events in atrial fibrillation) study, apixaban 5 mg twice daily was compared with adjusted dose warfarin in a randomized, double-blind trial involving 18,201 patients with AF and at least one additional risk factor for stroke. The primary outcome was ischemic or hemorrhagic stroke or systemic embolism. In ARISTOTLE, apixaban reduced the primary outcome by 21% compared with warfarin. The reduction was significant and supports the superiority of apixaban over warfarin. Apixaban also significantly reduced all-cause mortality and major bleeding rates.[27]

Antiplatelet Drugs for Stroke Prevention in Atrial Fibrillation

Three primary prevention and three secondary prevention trials have shown that in patients with AF, aspirin reduces the annual incidence of stroke from 5.2% to 3.7% for primary prevention and from 12.9% to 10.4% for secondary prevention. Aspirin was not associated with any significant increase in the rate of intracranial hemorrhage or the rate of major extracranial bleeding. This means that aspirin might prevent about 10 to 20 strokes per 1000 patient-years of treatment, depending on baseline patient characteristics and baseline risk of stroke. The relative benefits and risks of aspirin versus warfarin have been studied in three trials, all of which showed that dose-adjusted warfarin (target INR, 2.0-3.0) was associated with half the risk of stroke compared with aspirin monotherapy. Similarly, for patients with AF who are at high risk of stroke, adding aspirin to low-intensity, fixed-dose warfarin was not as effective in preventing stroke or systemic thromboembolism as adjusted-dose warfarin monotherapy targeting to an INR of 2.0 to 3.0. There was no difference in major bleeding rates.

Dual antiplatelet therapy has been compared with warfarin for the prevention of thromboembolism in patients with AF in the ACTIVE W (Atrial Fibrillation Clopidogrel Trial with Irbesartan for Prevention of Vascular Events) trial. The trial was stopped prematurely because of a clear benefit of warfarin arm over the combination of clopidogrel plus aspirin. Of note, the incidence of major bleeding was similar in the two groups.[28] The ACTIVE-A study compared the clopidogrel–aspirin combination with aspirin alone in moderate- to high-risk patients with AF for whom VKA therapy was unsuitable. The trial showed that the addition of clopidogrel to aspirin reduced the risk of major vascular events and concluded that combination antiplatelet therapy was better than aspirin alone for the prevention of thromboembolism in patients with AF. Nonetheless, major bleeding rates with aspirin plus clopidogrel were more than 50% greater than with aspirin alone and were similar to rates seen with anticoagulation.[29]

Practical Considerations

The decision to treat an individual patient should be based on the balance between the risk of thromboembolism if left untreated and the risks of thromboembolism and hemorrhage if treated. The patient's willingness to accept the potential risks, costs, and inconvenience related to treatment and the limitations of the available health care system should also be considered. Finally, one should also keep in mind that the current profile of individual risk of thromboembolism and bleeding complications (see above) is imperfect and continues to be refined as new data emerge.

The choices of thromboprophylaxis for AF patients include warfarin, which is the most effective but also the most risky treatment, and aspirin, which is less effective but safer than warfarin. The ideal treatment strategy is the one in which patients at high risk of stroke and low risk of hemorrhage are treated with warfarin and patients at low risk of stroke or high risk of hemorrhage are treated with aspirin or no antithrombotic treatment.

Based on current guidelines, aspirin or no antithrombotic therapy (the latter preferred) should be considered for individuals in AF who are at "truly low risk" of stroke, such as those without any of the independent risk factors listed earlier (i.e., CHA_2DS_2-VASc score of 0). Oral anticoagulation therapy (whether with warfarin or one of the new oral anticoagulants) is the treatment of choice for individuals with chronic AF who have an annual risk of stroke greater than 4% (i.e., CHA_2DS_2-VASc score >1) and an acceptable risk of hemorrhage. For patients at intermediate risk (i.e., CHA_2DS_2-VASc score of 1), either treatment is reasonable, but oral anticoagulation therapy is preferred. For patients whose risks of thromboembolism and hemorrhage are both high, identifying a treatment strategy can be difficult and may ultimately be guided by the patient's preferences.[10]

Patients on aspirin or no antithrombotic therapy should be reviewed regularly, and their treatment may change because individualized risk changes over time; such change occurs in 10% to 15% of people being treated with aspirin per year.

The range of VKA therapy intensity (INR) that provides the best balance between the prevention of thromboembolism and the occurrence of bleeding appears to be between 2.0 and 3.0 but may be higher in patients at greater risk of thromboembolism, particularly those with prosthetic valves. Although some advocate a lower INR intensity for those at risk of bleeding (e.g., INR 1.8-2.5), the bleeding rate is lowest with an INR below 3.0 with no further decline with an INR below 2.0. Hence, there is little reason to aim for a lower target INR, especially because the risk of thromboembolism increases with an INR below 2.0.

When cessation of warfarin is required because of scheduled invasive procedures, it is necessary to stratify the bleeding risk associated with the procedure and the short-term risk of thromboembolism. Warfarin can be ceased 5 days before a high bleeding risk procedure and continued at a decreased dose for a minor bleeding risk procedure. In either case, therapy should be reinstituted as soon as possible. For patients at high risk of thromboembolism, heparin or low-molecular-weight bridging during warfarin cessation is the preferred strategy.[10,12]

Nonpharmacologic Approaches to Prevention of Thromboembolism

A promising option for patients with AF who cannot safely be subjected to oral anticoagulation is obliteration of the LAA to remove the main anatomic source of thrombus formation. In addition to direct surgical amputation or truncation of the LAA, several methods are under development to achieve this with intravascular catheters or via a transpericardial approach. The most recent study, PROTECT-AF

(Protection in Patients With Atrial Fibrillation), reported that the WATCHMAN LAA occlusion device was noninferior to warfarin for stroke prevention, suggesting that this option could be considered or patients could not tolerate anticoagulants. However, the long-term safety and efficacy of these procedures remain to be determined.[30]

FUTURE DIRECTIONS

Future studies are planned to evaluate the safety and effectiveness of new antiarrhythmic drugs and procedures as well as new thromboprophylaxis strategies in AF patients. New oral anticoagulants—such as oral direct thrombin inhibitors and oral factor Xa inhibitors—are promising alternatives to warfarin. In general, these new drugs have fewer drug or food interactions and, most importantly, do not require anticoagulation monitoring. In fact, dabigatran and rivaroxaban have already been approved for stroke prevention in AF, and based on evidence from recent clinical trials, apixaban will get approval, too.

In conclusion, antithrombotic management of AF patients will change dramatically the following years. Available evidence indicates that dabigatran and apixaban are better than warfarin for stroke prevention in patients with AF. Rivaroxaban was proved as effective as warfarin in an exceedingly high-risk population, and patients can also benefit from its optimal pharmacokinetic profile. Warfarin remains a safe and effective option, limited by its narrow therapeutic range, the need for close monitoring, and the multiple food and drug interactions. The low cost of VKAs remains their strongest and most appreciated quality. Finally, for patients not suitable for anticoagulant treatments, closure of the LAA with a percutaneous LAA occluder seems a promising alternative, with encouraging initial results.

CHAPTER 150

PERIPHERAL ARTERY DISEASE

Reena L. Pande and Mark A. Creager

Peripheral artery disease (PAD) is an important manifestation of systemic atherosclerosis with significant morbidity and mortality.[1,2] PAD affects the lower extremities and is defined as a stenosis or occlusion in the aorta or in the arteries supplying blood to the legs, including the iliac, femoral, popliteal, or infrapopliteal vessels (peroneal, posterior tibial, and anterior tibial arteries). Stenosis is typically caused by atherosclerosis. Nonatherosclerotic causes of vascular disease also can obstruct the peripheral arteries (see later discussion). There are two major clinical consequences of PAD. First, PAD can cause leg symptoms that include intermittent claudication, which impairs walking ability and diminishes quality of life, and rest pain, which occurs when there is critical limb ischemia. Second, as an atherosclerotic disorder, PAD is associated with as much as a four- to sixfold increased risk of cardiovascular death, myocardial infarction (MI), and stroke. This chapter reviews the epidemiology, pathophysiology, and management of PAD.

EPIDEMIOLOGY

Prevalence and Incidence

The prevalence of PAD has been determined from several epidemiologic studies. Early studies determined the prevalence of PAD from the presence of symptoms, such as intermittent claudication, or history of peripheral revascularization. Many patients with PAD are asymptomatic, and the use of noninvasive diagnostic testing, specifically measurement of the ankle-brachial index (ABI), has provided further clarification of the overall prevalence of disease. In most of these studies, an ABI of 0.90 or less was used to define PAD. Based on data from the National Health and Nutrition Examination Survey (NHANES), the prevalence of PAD in adults 40 years of age or older is estimated to be 5.9%, accounting for approximately 7.1 million adults in the United States alone.[3] There is a sharp increase in the prevalence of PAD with increasing age.[4,5] In the Rotterdam study, which enrolled 7715 subjects ages 55 years and older, the prevalence of PAD ranged from 6.6% in men 55 to 59 years of age to 52.0% in men ages 85 years or older and from 9.5% to 59.6% in the corresponding age categories in women.[4] A San Diego population study determined the prevalence of PAD to be 11.7% among an older adult population with a mean age of 66 years.[5] The German Epidemiological Trial on ABI (get ABI study), which evaluated an unselected group of 6880 individuals older than 65 years of age, found a prevalence of PAD of 19.8% in men and 16.8% in women.[6] The PARTNERS (PAD Awareness, Risk, and Treatment: New Resources for Survival) study was a United States–based observational study that examined a more selected population, including older adults (older than 70 years) and adults ages 50 to 69 years with a history of diabetes or smoking. The prevalence of PAD, determined by an office-based ABI measurement, was as high as 29% in this targeted primary care population.[7]

The incidence of PAD, which is largely based on the development of symptomatic disease, is less well established. Data from the Framingham Heart Study show an incidence rate of intermittent claudication of less than 0.4 per 100 per year in younger men (35-45 years) and a rate as high as 6 per 100 per year in older men (older than 65 years).[8] The incidence of symptomatic PAD is lower in women at most age groups, although the estimates are more comparable in the oldest age group. Estimates of the incidence of PAD based on ABI are less commonly reported. One such study reports an incidence of 1.7 per 1000 person-years for ages 40 to 54 years, 1.5 per 1000 person-years for ages 55 to 64 years, and 17.8 per 1000 person-years for ages 65 years and older.[9] When the diagnosis of PAD is based on ABI alone, the differences in incidence between men and women are less evident. In the Cardiovascular Health Study, for example, there are no gender differences in the incidence of PAD based on ABI after adjusting for cardiovascular risk factors.[10] At the other end of the spectrum, critical limb ischemia (CLI) represents only 1% to 2% of the patients with PAD. The incidence of CLI is estimated to be approximately 400 to 1000 per million individuals per year.[2]

Risk Factors

Atherosclerotic risk factors, including smoking, diabetes, hypertension, hyperlipidemia, and inflammation, contribute to the development of PAD.

In virtually all population-based studies, smoking has been one of the strongest risk factors for PAD. The risk is highest for current smokers compared with nonsmokers, with a two to four times increased odds of PAD,[11] and the risk of PAD increases in a dose-dependent manner relative to the number of cigarettes smoked and the duration of tobacco use.[12-14] In the Women's Health Study, smoking more than 15 cigarettes per day increased the risk of incidence of PAD approximately 17-fold, and the risk was lower in former smokers than in active smokers.[15] In the Edinburgh Artery Study, smoking was two to three times more likely to cause lower extremity PAD compared with coronary artery disease (CAD).[12,16]

Diabetes is also a potent risk factor for PAD and increases the risk of PAD by two- to fourfold. Data from the Rotterdam study and the San Luis Valley Diabetes study reveal that upwards of 12% to 20% of individuals with PAD have coexisting diabetes.[4,17] Moreover, the risk of PAD increases depending on the duration and severity of diabetes. In the Strong Heart Study, individuals with PAD had a more than twofold higher prevalence of diabetes compared with those without PAD, and the diabetes tended to be of longer duration (11.7 vs. 8.4 years, $P < .001$) and associated with higher glycosylated hemoglobin levels.[18] Patients with PAD who have concomitant diabetes are also more likely to develop intermittent claudication and ischemic ulceration and to require major amputation compared with those without diabetes.[19,20]

Hypertension is a more modest risk factor for the development of PAD compared with its importance as a risk factor for coronary and cerebrovascular disease.[1] Although evidence suggests that hypertension increases the prevalence of PAD by 1.5- to 2.2-fold, the association of hypertension with incident or symptomatic PAD is less clear. Among American Indians in the Strong Heart Study, those with PAD had a higher mean systolic blood pressure, and the prevalence of PAD was significantly higher in those with established hypertension.[18] In the Framingham Heart Study, hypertension increased the risk of

developing intermittent claudication.[8] However, in the Whitehall study of more than 18,000 men ages 40 to 64 years, there was no significant association between elevated blood pressure and claudication symptoms.[21] Similarly, in the ARIC (Atherosclerosis Risk in Communities) study, there was no association of hypertension with incident PAD in subjects with diabetes.[22] In the Women's Health Study, however, the risk of incident PAD increased by 43% with every 10-mm Hg increase in systolic blood pressure.[23]

Dyslipidemia, specifically elevated total cholesterol, low-density lipoprotein (LDL) cholesterol and triglycerides, and reduced high-density lipoprotein (HDL) cholesterol, is associated with PAD. Epidemiologic studies, such as the Cardiovascular Health Study and the Framingham Heart Study, have shown that a 10-mg/dL increase in total cholesterol increases the risk of PAD by 5% to 10%.[10,24] In the Strong Heart study, individuals with PAD had significantly higher levels of total cholesterol, triglycerides, and LDL cholesterol.[18] The Whitehall study also demonstrated that an elevated total cholesterol level is associated with symptoms of intermittent claudication.[21]

Chronic renal insufficiency has been recognized to be significantly associated with PAD in several studies. In the NHANES, renal insufficiency (defined as a glomerular filtration rate <60 mL/min) was associated with a 2.5-fold higher odds of PAD even after adjustment for other cardiovascular risk factors.[25] In the Heart and Estrogen/Progesterone Replacement (HERS) study, renal insufficiency was also associated with an increased risk of incident peripheral vascular events, including revascularization and amputation.[26] Moreover, renal insufficiency increases the mortality risk in patients with PAD irrespective of other risk factors, including diabetes.[27,28]

Several other nontraditional factors have been associated with PAD. Markers of systemic inflammation, such as C-reactive protein (CRP), are elevated in patients with PAD. In the Physicians' Health Study, the risk of developing symptomatic PAD was approximately twofold higher in those in the highest CRP quartile compared with those in the lowest quartile.[29] Other markers of inflammation, such as soluble intercellular adhesion molecule 1 (sICAM-1), a leukocyte adhesion molecule, are also associated with PAD in this population and in the Women's Health Study.[30,31] Insulin resistance is also associated with PAD. In NHANES, individuals in the highest quartile of HOMA-IR (homeostasis model of insulin resistance) had a twofold increased odds of PAD compared with those in the lowest quartile.[32] The protective effect of bilirubin, an endogenous antioxidant, was explored in NHANES; there was evidence of an inverse association between total serum bilirubin levels and PAD.[33] The impact of genetics on the development of PAD has not been well explored, but a family history of PAD has been associated with development of PAD.[34]

PATHOBIOLOGY

Atherosclerosis is a progressive vascular disease characterized by lipid accumulation and formation of plaque in the arterial walls (see Chapter 146). The pathophysiology of atherosclerosis includes endothelial dysfunction, vascular inflammation, and cellular proliferation.[35] Early in the atherogenic process, recruitment of inflammatory cells and accumulation of lipids promote development of a lipid-rich atheroma. Inflammation promotes the elaboration of proteases that weaken the vessel wall and allow positive remodeling with outward expansion of the arterial wall to accommodate the intimal expansion that occurs as a result of plaque formation. Although positive remodeling initially preserves the arterial lumen, continued plaque growth results in progressive narrowing of the lumen, which then limits blood flow and oxygen supply to target organs. This process may be enhanced by biomechanical factors, such as turbulent blood flow, particularly in areas of altered shear stress. This phenomenon is of particular significance at branch points along the arterial tree, which are predisposed to atherosclerotic plaque formation.

Increasingly, it has been recognized that atherosclerotic plaque formation is a dynamic biologic process that exhibits marked heterogeneity; some plaques remain "stable", but others have a more "unstable" pathophysiology. Stable atherosclerotic plaques may be asymptomatic or symptoms can occur with exertion if demand exceeds supply. On the other hand, "vulnerable" or unstable plaques are prone to acute rupture, and superimposed thrombi may cause sudden arterial insufficiency. Studies have shown that acute thrombosis is not restricted to plaques that produce stenosis; many lesions without flow-limiting disease are prone to rupture. Evidence suggests that disruption of the fibrous cap overlying the atheroma is promoted by proinflammatory cytokines. Plaque disruption exposes the highly prothrombotic lipid-rich core of the atheroma to the blood, a process that triggers platelet aggregation and fibrin formation.

Although PAD is mostly caused by atherosclerosis, other causes include thromboembolism, atheroembolism, vasculitides (e.g., thromboangiitis obliterans, giant cell arteritis, Takayasu arteritis), trauma, popliteal artery entrapment, cystic adventitial disease, fibromuscular dysplasia, and endofibrosis of the iliac artery (Table 150-1). Nonvascular causes of leg pain should also be considered in the differential diagnosis, including lumbosacral spine disease (causing pseudoclaudication), acute and chronic venous diseases, hip or knee osteoarthritis, myositis, and others (Table 150-2).

Table 150-1 Nonatherosclerotic Causes of Peripheral Artery Disease

- Thromboembolism
- Atheroembolism
- Vasculitides
 - Large vessel vasculitides, such as giant cell arteritis and Takayasu arteritis
 - Small vessel vasculitides, such as thromboangiitis obliterans (Buerger disease)
- Trauma
- Popliteal artery entrapment
- Cystic adventitial disease
- Fibromuscular dysplasia
- Iliac artery endofibrosis

Table 150-2 Nonarterial Causes of Leg Pain (Differential Diagnosis for Intermittent Claudication Symptoms)

- Lumbar radiculopathy
- Spinal stenosis
- Hip or knee osteoarthritis
- Myositis
- Venous claudication

CLINICAL MANIFESTATIONS

The majority of patients with PAD are asymptomatic at presentation. Typical claudication symptoms are present in only 10% to 35% of patients and CLI in 1% to 2%.[1] The classic symptoms of PAD include intermittent claudication and rest pain, the latter occurring in patients with CLI. Intermittent claudication is defined as exertional discomfort in the muscles of the lower extremities that is variably described as pain, aching, burning, fatigue, or heaviness. Symptoms arise with leg exercise, typically walking, and are relieved after a predictable duration of rest (usually <10 minutes). Intermittent claudication occurs with effort and not at rest, and symptoms do not abate until activity ceases; a change in position is unnecessary. Although many patients with PAD report atypical symptoms, most have impaired walking ability exemplified by reduced walking speed or distance.[36] CLI arises when there is inadequate perfusion to meet the resting metabolic demands of the tissues. Patients with CLI have pain at rest, typically affecting the toes, feet, or both; they may have accompanying tissue loss with nonhealing ulcers, tissue necrosis, or gangrene.

DIAGNOSIS

The diagnosis of PAD is often evident from the history and physical examination. An important diagnostic feature is diminished or absent pulses in the legs. The examiner should palpate the femoral, popliteal, dorsalis pedis, and posterior tibial pulses. Absence of selected pulses provides insight into the location of critical stenoses. The groin should be auscultated for femoral artery bruits, which may be indicative of turbulent flow from atherosclerotic plaque. Other findings suggestive of PAD include pallor of the soles of the feet upon leg elevation and the development of rubor when the feet are then placed in the dependent position. Signs of chronic limb ischemia include muscle atrophy; hair loss; thickened nails; and in severe stages, cyanosis, pallor, and coolness of the skin of the feet.

Ankle-Brachial Index

The ABI is a simple, noninvasive test for the diagnosis of PAD. Normally when measured in the supine position, the systolic blood pressure in the legs is the same as that in the arms. However, pulse wave amplification may yield a higher systolic pressure at the ankle. Therefore, the ratio of the ankle to the brachial systolic pressure, designated as the ABI, should be 1.0 or slightly higher. A diminution of the ankle systolic blood pressure relative to the brachial artery pressure indicates a stenosis or occlusion in the aorta or in arteries of the lower extremities.

The ABI is determined by measuring the systolic blood pressure in both arms (brachial arteries) and in both ankle vessels (dorsalis pedis and posterior tibial arteries) after the patient has been in the supine position for at least 5 to 10 minutes.[1] To measure these pressures, sphygmomanometric cuffs are sequentially inflated at each location to suprasystolic pressures. The onset of systole with subsequent cuff deflation is determined with a Doppler device that is placed over the artery. The ABI for each leg is calculated by dividing the higher of the two ankle pressures by the higher of the two arm pressures. Taking into account the intrinsic variability in blood pressure over time, an ABI of 0.90 or less is indicative of PAD. At this threshold, the ABI has excellent sensitivity (90%) and specificity (>95%) compared with angiography.[37] An ABI of 0.91 to 1.0 is considered borderline.[38] Vascular calcification, as often occurs in patients with diabetes or renal insufficiency, may preclude accurate determination of systolic blood pressure at the ankle. For this reason, an ABI that is markedly elevated (e.g., >1.4) is considered inaccurate and indicative of vascular calcification. In this circumstance, other simple noninvasive diagnostic tests, such as assessment of the toe-brachial index or pulse volume recordings, may be useful to detect PAD. In some cases of PAD, the ABI is normal at rest. This is particularly common in patients who have proximal disease, such as iliac artery stenosis, and an extensive collateral circulation. In such cases, measurement of the ABI after walking will detect a decrease in the ankle systolic pressure relative to brachial artery systolic pressure, thereby revealing the presence of PAD.

Noninvasive Imaging for Diagnosis

Several other noninvasive tests may help in the diagnosis of PAD and in the identification of sites of stenosis. These tests include segmental pressures with pulse volume recordings, duplex ultrasonography, computed tomography angiography (CTA), magnetic resonance angiography (MRA), and conventional contrast angiography. When measuring segmental leg pressures, systolic blood pressure measurements are obtained at multiple levels in the leg, typically in the upper thigh, lower thigh, upper calf, ankle, and across the metatarsal region of the foot. Systolic blood pressures in these sites are then compared with the higher of the arm systolic blood pressures. A significant drop in blood pressure (>20 mm Hg) from one level to the next can localize arterial stenosis with a high degree of precision. An upper thigh pressure that is lower than the arm pressure indicates stenosis in the distal aorta or in the iliac or femoral arteries (or both). In patients with vascular calcification, measurement and interpretation of segmental pressures are unreliable. Pulse volume recordings can also be obtained at each level using a plethysmographic instrument that records the change in volume of that limb segment with each arterial pulsation. A normal waveform resembles an arterial waveform with a brisk upstroke and a prominent dicrotic notch in the downstroke (Fig. 150-1). Abnormal waveforms, which appear distal to a hemodynamically significant stenosis, have a parvus et tardus appearance with a blunted upstroke and decreased pulse amplitude.

Duplex ultrasonography is used both for diagnosis of PAD and for the surveillance of bypass grafts or stents after revascularization procedures. Color Doppler can identify abnormal flow with turbulence and Doppler aliasing suggesting an area of stenosis (Fig. 150-2). Pulse Doppler sampling can then confirm flow acceleration in a diseased segment. A peak systolic velocity (PSV) in a diseased segment that is more than twice the PSV in the proximal segment indicates a hemodynamically significant stenosis of at least 50%. Duplex ultrasonography has been shown to be accurate and reproducible with a sensitivity and specificity of 82% and 92%, respectively, compared with angiography.[39] However, duplex ultrasonography is a time-consuming procedure and is operator dependent.

The most commonly used imaging modalities for diagnosis of PAD are MRA and CTA. The two tests have comparable diagnostic accuracy for identification of arterial stenosis. MRA takes advantage of the inherent magnetic properties of human tissue. Pulsed magnetic sequences cause protons within cells to spin and align, generating a frequency of energy that can be detected by the scanner. Various tissues have different frequencies that allow delineation of the structures and tissues within the body. The addition of the paramagnetic contrast agent gadolinium allows selective imaging of moving blood (Fig. 150-3). This flow-related enhancement of the vasculature produces angiographic images. Although MRA has the advantage of using nonionizing radiation, it has several limitations. The test cannot be performed in patients with implanted cardiac devices or other metal objects. Although MRA can be used in patients with vascular stents, ferromagnetic metals in the stents may produce artifacts that limit assessment of the stented vessel. MRA is contraindicated with renal insufficiency because gadolinium administration in such patients can be associated with nephrogenic systemic fibrosis (NSF).[40] Claustrophobia may also preclude MRA.

Similar to MRA, CTA also has excellent specificity and sensitivity for detection of arterial stenosis. The advent of large-volume imaging with multidetector scanners enables rapid image acquisition and high resolution. Advantages of CTA include the capacity to rapidly visualize the entire arterial tree and to delineate vascular calcification and intraluminal thrombus. Limitations of the test include the exposure to ionizing radiation and the need for iodinated contrast agents, which is problematic in patients with renal impairment. In addition, extensive arterial calcification may prevent accurate determination of the degree of stenosis.

Magnetic resonance angiography and CTA have largely supplanted conventional angiography for PAD diagnosis. Nonetheless, invasive contrast angiography remains the gold standard for the diagnosis of PAD. Conventional angiography is most useful in situations in which concurrent endovascular interventions are planned or in preparation for surgical revascularization. Limitations to conventional angiography include the invasive nature of the procedure, the need to administer iodinated contrast, and the radiation exposure. Potential complications include arteriovenous fistula or pseudoaneurysm formation at the access site, atheroembolism, dissection, and contrast-induced renal insufficiency. Alternatives to iodine-based contrast agents, such as carbon dioxide and gadolinium, can be used when administration of iodinated contrast is contraindicated.

PROGNOSIS

Prognostic considerations are broadly divided into limb outcomes and overall cardiovascular outcomes. Limb prognosis is dependent on

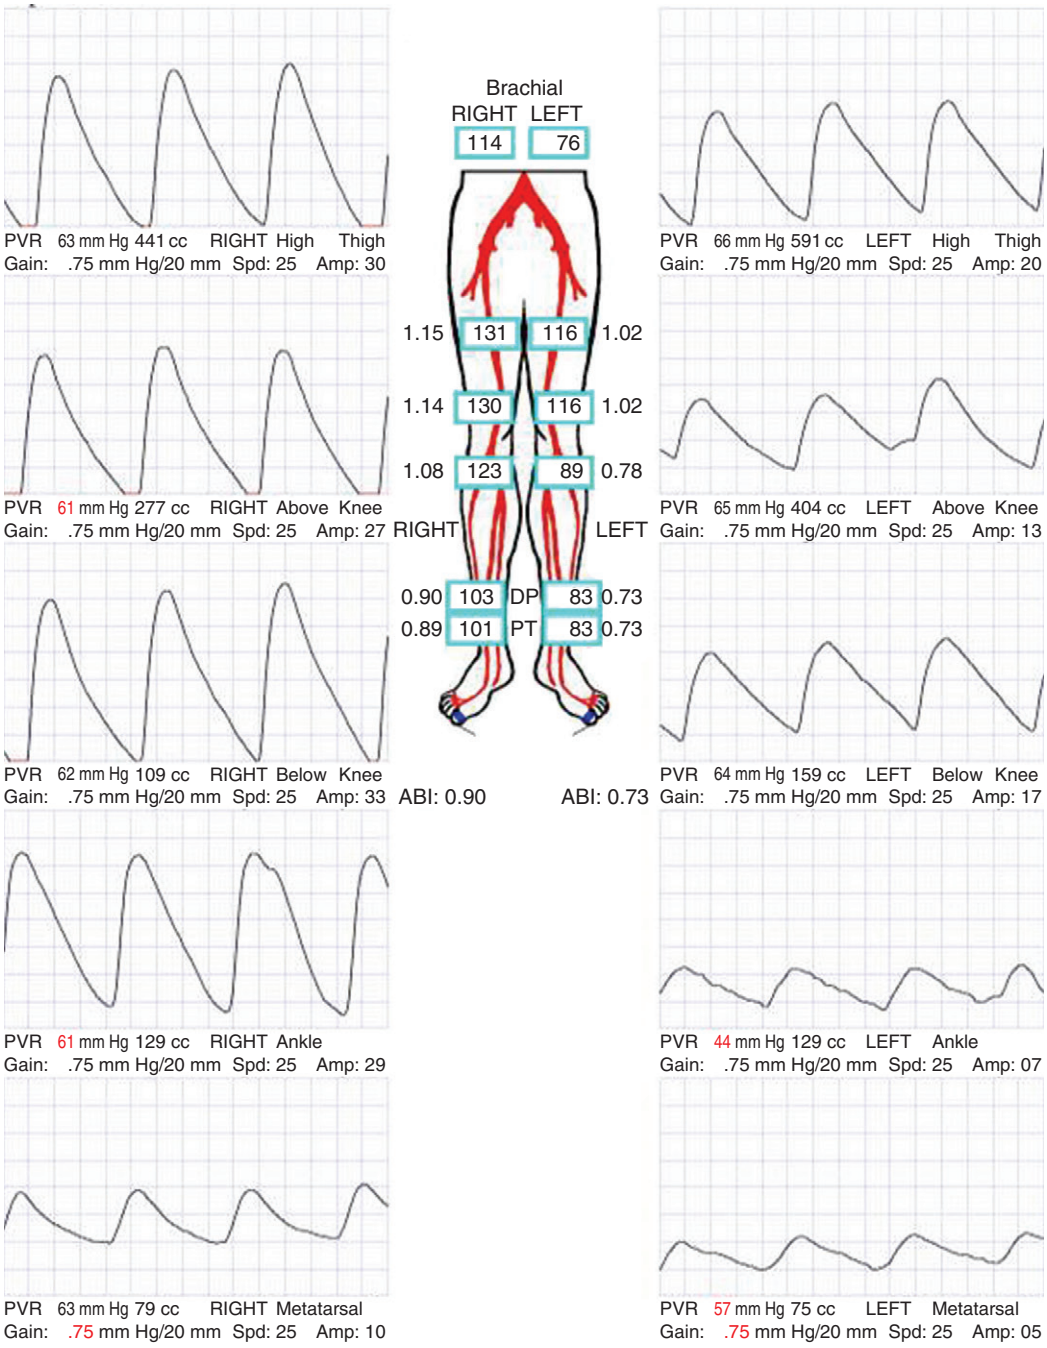

Figure 150-1 SEGMENTAL LEG PRESSURE MEASUREMENTS AND PULSE VOLUME RECORDINGS (PVRs). The ankle-brachial index (ABI) is normal in the right leg. The greater than 20-mm Hg drop in systolic blood pressure between the lower thigh and the calf in the left leg suggests stenosis involving the distal left femoral artery, popliteal artery, or both. There is also evidence of blunting of the pulse volume recording with a parvus et tardus waveform. The significant difference in brachial artery systolic blood pressure is suggestive of left subclavian artery stenosis. *Amp,* amplitude; *Spd,* speed.

the severity of symptoms at initial presentation; concurrent risk factors, such as cigarette smoking and diabetes; and the likelihood of successful revascularization in those with threatened limb viability. Among patients with claudication symptoms, leg discomfort remains stable in the majority (≈70%-80%), worsens in about 10% to 20%, and progresses to CLI in a small percentage.[1] Prognosis is worst for those with CLI, which is associated with a mean amputation-free survival at 1 year of only 50%. Outcomes are worse for PAD patients who continue to smoke or have coexisting diabetes; such patients have even higher rates of ischemic ulceration and amputation.

Given the high risk of concomitant coronary and cerebrovascular disease, individuals with PAD are also at increased risk of MI, stroke, and cardiovascular death. The mortality rate is increased two- to fourfold in patients with PAD compared with those without this complication. A meta-analysis of 16 cohort studies from the ABI collaboration confirmed the association between PAD and mortality and firmly established a graded association of lower ABI with increased mortality.[41] In PAD patients, the risk of MI is increased by 20% to 60%, and the risk of stroke is increased by 40%.[42-45] The REACH registry found that the 1-year event rate for the composite of cardiovascular death, MI, and stroke was 6.2% in individuals with

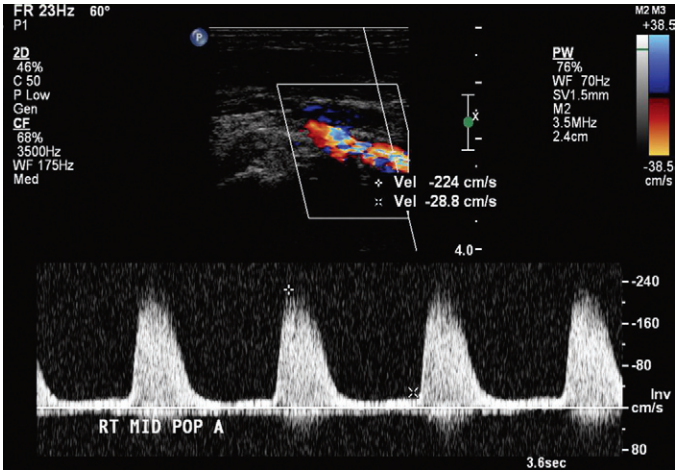

Figure 150-2 DUPLEX ARTERIAL ULTRASOUND DEMONSTRATING DOPPLER INTERROGATION OF THE POPLITEAL ARTERY. Turbulence of color Doppler flow indicates possible stenosis, confirmed by elevated peak systolic velocity, monophasic waveform, and spectral broadening.

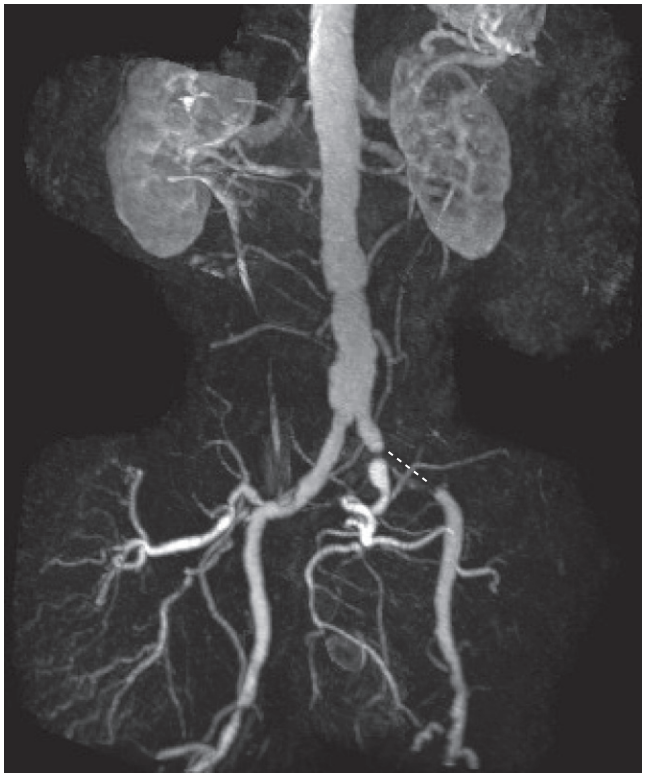

Figure 150-3 Representative projection imaging from a gadolinium-enhanced magnetic resonance angiogram demonstrating segmental occlusion of the left common iliac artery (indicated by *dashed white line*), as well as nonobstructive atherosclerotic disease in the distal aorta and more distally in the external iliac arteries.

PAD. The highest event rates were in those with polyvascular disease compared with rates in patients with atherosclerosis involving only one vascular bed.[46,47]

THERAPY

The major goals in the management of patients with PAD are to (1) reduce the risk of cardiovascular morbidity and mortality and (2) improve lower extremity symptoms and preserve limb viability. Aggressive cardiovascular risk factor modification is indicated for all patients with PAD. This includes treatment of dyslipidemia, hypertension, and diabetes (including regular foot care) and the use of antiplatelet therapy. Healthy lifestyle habits should be encouraged; these include smoking cessation, a diet enriched in fruits and vegetables and limited in saturated fats, and regular physical activity.[1]

Dyslipidemia

Treatment of dyslipidemia with statins decreases major cardiovascular events in patients with all manifestations of atherosclerosis. The 4S study (Scandinavian Simvastatin Survival Study) was one of the first to demonstrate a clear benefit of lipid-lowering therapy for secondary prevention in patients with atherosclerosis and dyslipidemia.[48] Subsequently, the Heart Protection Study demonstrated that statin therapy was associated with a 22% relative risk reduction in adverse cardiovascular events in patients with vascular disease, including PAD.[49,50] Current practice guidelines recommend statins for PAD patients in doses sufficient to lower LDL cholesterol levels below 100 mg/dL (for primary prevention) and below 70 mg/dL for secondary prevention.[1,51]

The appropriate management of non-LDL cholesterol (HDL and triglycerides) is less clear. Although reduced HDL levels are a risk factor for atherosclerosis, studies with medications that increase HDL levels and lower triglyceride levels have yielded conflicting results. The VA-HIT study (Veterans Affairs High-Density Lipoprotein Intervention Trial) showed that gemfibrozil reduced the risk of fatal coronary disease or nonfatal MI by 22% over a median of 5.1 years in patients with known CAD.[52] However, in a study of PAD patients, bezafibrate did not affect the rate of coronary events or stroke.[53] In addition, in the FIELD (Fenofibrate Intervention and Event Lowering in Diabetes) study, fenofibrate did not reduce coronary events in diabetics, although its use was associated with fewer nonfatal MIs and revascularization procedures.[54] Other agents, such as niacin or binding resins, reduce lipid levels, but their efficacy for reducing cardiovascular events has not been established.[55]

Hypertension

Treatment of hypertension is a critical component of the management of patients with atherosclerotic PAD. Such treatment reduces the risk of stroke, MI, and congestive heart failure. Management of hypertension should follow current guidelines.[56] Although there is concern that lower systemic blood pressure may exacerbate symptoms of claudication or CLI, the majority of patients experience no change in their symptoms.[57] Few studies have explored specific antihypertensive regimens in patients with PAD. The HOPE (Heart Outcomes Prevention) study demonstrated a 22% reduction in cardiovascular events with ramipril in patients with atherosclerotic disease, including patients with PAD defined as claudication symptoms, revascularization, or ABI below 0.90.[58,59] ONTARGET (Ongoing Telmisartan Alone and in Combination with Ramipril Global Endpoint Trial) demonstrated that telmisartan and ramipril produced similar reductions in the composite cardiovascular endpoint that included cardiovascular death, MI, stroke, or hospitalization for heart failure (16.7% and 16.5%, respectively; relative risk [RR], 1.01; 95% confidence interval, 0.94-1.09). However, the combination of telmisartan and ramipril was associated with more adverse events, including hypotension, syncope, and renal insufficiency.[60] In a substudy of the ABCD (Appropriate Blood Pressure Control in Diabetes) trial, intensive blood pressure lowering in PAD patients was associated with a 65% relative reduction in the risk of MI, stroke, or cardiovascular death compared with modest blood pressure–lowering therapy.[61]

Diabetes

In PAD patients with concomitant diabetes, the goals of diabetes care include control of hyperglycemia and special attention to

diabetic foot care. Not only is diabetes associated with adverse limb outcomes (increased risk of ischemic ulceration and amputation in PAD patients), but it also is associated with increased mortality. Aggressive glycemic control reduces both macrovascular events (MI, stroke, and death) and microvascular events (nephropathy, neuropathy, and retinopathy) in patients with type I diabetes.[62] Although aggressive glycemic control reduces microvascular events in individuals with type II diabetes, reductions in macrovascular events have not been shown.[63] Several recent studies, such as the ADVANCE (Action in Diabetes and Vascular Disease: Preterax and Diamicron Modified Release Controlled Evaluation), ACCORD (Action to Control Cardiovascular Risk in Diabetes) and Veterans Affairs Diabetes trials, have failed to show a reduction in cardiovascular events with aggressive treatments aimed at lowering the hemoglobin A1C to 6%.[64,65] Likewise, the PROactive study (Prospective Pioglitazone Clinical Trial In Macrovascular Events) failed to show a reduction in cardiovascular or limb outcomes (lower rates of extremity revascularization or amputation with pioglitazone) in patients with type II diabetes who were at risk for cardiovascular events. However, the study did show a significant 16% reduction in the secondary endpoint, a composite of total mortality, nonfatal MI, or stroke, with pioglitazone.[66] Consequently, although the optimal glycemic control required to reduce macrovascular complications in patients with type II diabetes remains unclear, guidelines recommend treatments that maintain the level of hemoglobin A1c below 7%.

Foot care is a critical component of diabetes management, particularly in those with PAD. Diabetes increases the risk of foot injury because of the associated peripheral neuropathy and decreased sensation, thereby increasing the risk of ulcer formation. Resting limb ischemia and amputation are more frequent in PAD patients with diabetes than in those without diabetes. Therefore, careful attention to foot care is imperative to prevent skin breakdown, infections, ulceration, and amputation.

Antiplatelet Therapy

Antiplatelet therapy is recommended for patients with atherosclerosis, including patients with symptomatic PAD.[38] The Anti-platelet Trialists' Collaboration meta-analysis showed a 22% to 32% reduction in the relative risk of stroke, MI, or vascular death in patients with high-risk vascular disease, including prior stroke or transient ischemic attack or MI.[67] In a subset of patients with evidence of PAD based on symptoms of claudication or prior lower extremity bypass or angioplasty, antiplatelet therapy also produced a 22% relative risk reduction. The meta-analysis included studies that evaluated a variety of antiplatelet agents, such as aspirin, dipyridamole, picotamide, and ticlopidine. The benefits of aspirin have been called into question with a recent meta-analysis showing no significant effect of aspirin on cardiovascular events in patients with PAD.[68] The largest of the studies included in this meta-analysis was the POPADAD (The Prevention Of Progression of Asymptomatic Diabetic Arterial Disease) study, which randomized patients with ABI below 0.99 and no known cardiovascular disease to 100 mg of aspirin or placebo and showed no significant difference between the groups (hazards ratio [HR], 0.98; 95% CI, 0.76-1.26). The AAA (Aspirin for Asymptomatic Atherosclerosis Trial) explored whether aspirin (100 mg/day) was of benefit in asymptomatic individuals with PAD diagnosed solely on the basis of an abnormal ABI.[69] Compared with placebo, aspirin had no effect on the composite endpoint of fatal or nonfatal MI, stroke, or revascularization. When clopidogrel was compared with aspirin in the CAPRIE trial, clopidogrel was associated with an 8% reduction in endovascular events.[70] The CHARISMA study showed no benefit of dual antiplatelet therapy with aspirin plus clopidogrel in patients with established CAD, cerebrovascular disease, or PAD or in patients with risk factors for these disorders.[71] In a post-hoc analysis that focused on patients with symptomatic or asymptomatic PAD, there also was no benefit of dual antiplatelet therapy for the primary endpoint. However, the risk of MI and repeat hospitalization for ischemic events were lower for dual antiplatelet therapy (HR, 0.63; 95% CI, 0.42-0.96 and HR, 0.81; 95% CI, 0.68-0.95, respectively).

Treatment of Lower Extremity Symptoms

Treatments that target the symptoms and signs of PAD are implemented to improve function and mobility and preserve limb viability. Established treatments can be broadly categorized into supervised exercise therapy, pharmacotherapy, and revascularization. Therapeutic angiogenesis has also been explored as a potential therapeutic option.

Exercise Therapy

Supervised exercise therapy improves walking distance by as much as 100% to 150% in patients with PAD.[72,73] Patients are recommended to walk on a treadmill or track three to five times per week for a duration of at least 45 minutes per session for 3 to 6 months. Exercise should continue until patients develop moderate to severe claudication; after a rest period, they should resume walking with the cycle repeated until the session is over. As patients improve, walking speed and treadmill grade can be increased. Supervised exercise programs are of greater benefit in PAD patients than home-based unsupervised training. However, a recent study showed that home-based therapy quantified by monitoring home activities can be of benefit.[74] The CLEVER (The Claudication: Exercise Versus Endoluminal Revascularization) trial showed that a 6-month supervised exercise training program in patients with aortoiliac disease and claudication produced a greater improvement in walking time than optimal medical therapy alone or stenting.[75] The mechanisms responsible for the benefits of exercise remain unclear. Potential mechanisms include collateral blood vessel development as a consequence of upregulation of angiogenic growth factors, endothelium-dependent vasodilation because of enhanced nitric oxide bioavailability, more efficient walking biomechanics, and improved skeletal muscle metabolism.

Pharmacologic Therapies

Although many medications have been evaluated, few have improved the symptoms of claudication in PAD patients. Only two medications are approved by the Food and Drug Administration; cilostazol and pentoxifylline. Cilostazol is a phosphodiesterase 3 (PDE3) inhibitor that has both vasodilator and antiplatelet properties. The precise mechanism by which cilostazol confers benefit in patients with PAD is unknown. Several randomized trials have shown that compared with placebo, cilostazol produces an approximately 50% increase in walking time and improves perceived quality of life.[76] Because other PDE3 inhibitors (e.g., milrinone) have been linked to increased mortality in patients with congestive heart failure, cilostazol should not be used in this subpopulation of PAD patients. However, cilostazol has not been associated with an increase in mortality.[77] Evidence for the efficacy of pentoxifylline, a hemorrheologic agent, is less robust than that for cilostazol, and pentoxifylline is less likely to be of clinical benefit.[76]

Statins have also been explored for the treatment of claudication to exploit their pleiotropic effects, such as attenuation of inflammation. One study showed an improvement in pain-free walking time with atorvastatin but no significant increase in maximal walking time.[78] Other studies revealed an increase in walking time with simvastatin.[79,80] A recent study, however, showed no benefit of niacin plus lovastatin on walking times compared with placebo.[81]

Revascularization

Lower extremity revascularization is reserved for patients with CLI or lifestyle-limiting claudication symptoms despite maximal medical

therapy. For those with CLI, prompt revascularization is necessary. Revascularization in such patients may alleviate resting limb pain, accelerate the healing of ulcers, and reduce infection. In patients with claudication, revascularization can lessen leg discomfort and improve quality of life. Options for revascularization include endovascular (percutaneous) intervention or open surgical revascularization.

Endovascular intervention, which includes percutaneous transluminal balloon angioplasty (PTA) and endovascular stenting, is increasingly being used as a less invasive option for revascularization in patients with PAD. The advances in technology of balloon-expandable and self-expanding stents have widened the population of patients with suitable anatomic lesions that stands to benefit from these procedures. Eligible patients include those with severe or disabling symptoms of claudication and those with limb-threatening ischemia. Clinical outcomes for endovascular revascularization depend on the type and length of the lesions. Treatment of stenoses is more likely to be successful than treatment of total occlusions, and success is influenced by a variety of morphologic characteristics, as delineated in the TASC (TransAtlantic Inter-Society Consensus) Working Group classification for iliac and for femoropopliteal lesions.[2] Durability and patency are greatest for iliac artery lesions; the likelihood of long-term patency with endovascular interventions is lower with disease in more distal arteries. Patency rates decrease with increasing lesion length, the presence of diffuse disease or multiple lesions, and poor run-off, as well as other adverse patient characteristics, such as diabetes, active smoking, and renal failure.[1]

For aortoiliac interventions, endovascular treatment affords excellent long-term patency, especially when combined with stenting. Five-year patency rates are approximately 94% and are comparable to rates achieved with surgical intervention. Results are less durable for femoropopliteal PTA, with patency rates of 50% to 70% at 3 to 5 years. It is less clear that stenting improves outcomes in the femoropopliteal arteries. One study comparing nitinol stents with PTA alone in patients with femoropopliteal artery stenosis with lesions averaging approximately 130 mm in length revealed lower rates of restenosis and improved walking time in patients treated with stenting.[82] However, for shorter lesions, data from the FAST study (Femoral Artery Stenting Trial) found no difference in restenosis rates with nitinol stents versus PTA.[83] Compared with bare-metal stents, drug-eluting stents (DES) have shown promise for femoral artery revascularization; a recent study showed improved survival free of major vascular events (death, amputation, or revascularization) with DES.[84] The role for drug-eluting balloons is unclear. Preliminary data suggest that local application of paclitaxel with a drug-eluting balloon during femoropopliteal artery revascularization reduces the rates of restenosis and target vessel revascularization at 6 months compared with uncoated balloon angioplasty.[85] Endovascular treatment of infrapopliteal artery stenosis is typically reserved for patients with limb ischemia. Recent studies have shown that DES use is safe for below-knee limb ischemia and may improve outcomes. For example, in the PARADISE (Preventing Amputations Using Drug Eluting Stents) study, a prospective, nonrandomized study of 106 patients, the 3-year amputation-free survival rate after DES implantation for treatment of limb ischemia involving the infrapopliteal vessels was 68%.[86] Several randomized clinical trials are currently underway to further address the utility of DES in the peripheral vasculature.

Surgical revascularization remains the gold standard for peripheral revascularization with the choice of operation depending on the location of the stenosis. Options include (1) aortoiliac or aortofemoral reconstruction for proximal disease involving the aorta or iliofemoral vessels, (2) femoral-popliteal bypass (either above- or below-knee popliteal) for superficial femoral artery or popliteal artery disease, and (3) femoral-distal (tibial or peroneal) for distal arterial stenosis. Aortobiiliac or aortobifemoral bypass graft surgery for aortoiliac occlusive disease ("inflow") produces excellent long-term results with 5-year patency rates ranging from 85% to 90%.[87] Surgical treatment of infrainguinal disease ("outflow") also produces durable results, although outcomes depend on the type of bypass conduit used. Vein grafts are the most durable; femoral-popliteal vein bypass grafts have an expected 5-year patency rate of approximately 66%. The 5-year patency rate for prosthetic grafts, such as polytetrafluoroethylene (PTFE), is lower, about 47%.[1] Limitations of surgical interventions include the need for general anesthesia and the attendant risk of cardiovascular events and death associated with major noncardiac surgery in patients with atherosclerosis. Given the potential for coexistent cardiovascular disease, preoperative assessment is important to identify and limit the risk of cardiovascular events in vascular surgery patients.[88]

Therapeutic Angiogenesis

Several clinical trials have explored the utility of angiogenic growth factors for improvement of walking time in patients with claudication or for promotion of healing and preservation of limb viability in patients with CLI. Angiogenic factors investigated have included vascular endothelial growth factor, fibroblast growth factor, hepatocyte growth factor, and hypoxia inducible factor-1 α.[89,90] Despite encouraging results with these agents in animal models of hindlimb ischemia, none of the human studies has demonstrated a benefit of gene therapy. It is not known whether the lack of success is due to the choice of gene, mode of delivery, or other factors.

Early data on infusion of endothelial progenitor cells (EPCs) has been more promising. In experimental models, EPC infusion in hindlimb ischemia models promotes angiogenesis, as indicated by capillary density, and reduces the need for amputation.[91] Preliminary studies in humans suggest that infusion of autologous CD34 cells may reduce amputation rates in patients with CLI.[92]

FUTURE DIRECTIONS

A better understanding of the factors that contribute to intermittent claudication and CLI is needed to craft innovative and durable therapeutic interventions for management of the limb complications of PAD. More studies are needed to explore the role of therapeutic angiogenesis and to identify the optimal growth factors, stem cells, and modes of delivery. A critical component of PAD management is treatment to reduce the risk of cardiovascular events. Greater knowledge dissemination regarding PAD diagnosis is key to early diagnosis and implementation of risk factor modification therapies.

CHAPTER 151

ANTITHROMBOTIC DRUGS

Jeffrey I. Weitz

Arterial or venous thromboembolism is a major cause of morbidity and mortality. Arterial thrombosis is the most common cause of acute myocardial infarction, ischemic stroke, and limb gangrene, whereas deep venous thrombosis leads to pulmonary embolism, which can be fatal, and to the postthrombotic syndrome. Most arterial thrombi are superimposed on disrupted atherosclerotic plaque because plaque rupture exposes thrombogenic material in the plaque core to the blood.[1] This material then triggers platelet aggregation and fibrin formation, which results in the generation of a platelet-rich thrombus that can temporarily or permanently occlude blood flow. In contrast to arterial thrombi, venous thrombi rarely form at sites of obvious vascular disruption.[1] Although they can develop after surgical trauma to veins, or secondary to indwelling central venous catheters, venous thrombi usually originate in the valve cusps of the deep veins of the calf or in the muscular sinuses where they are triggered by stasis. Sluggish blood flow in these veins reduces the oxygen supply to the avascular valve cusps. Endothelial cells lining the valve cusps become activated and express adhesion molecules on their surface. These adhesion molecules tether tissue factor–bearing leukocytes and microparticles to the surface of activated endothelial cells, where the tissue factor triggers coagulation. Local thrombus formation is exacerbated by reduced clearance of activated clotting factors as a result of impaired blood flow. If the calf vein thrombi extend into more proximal veins of the leg, thrombus fragments can dislodge, travel to the lungs, and produce a pulmonary embolism.

Arterial and venous thrombi are composed of platelets and fibrin, but the proportions differ. Arterial thrombi are rich in platelets because of the high shear in the injured arteries. In contrast, venous thrombi, which form under low-shear conditions, contain relatively few platelets and are predominantly composed of fibrin and trapped red cells. Because of the predominance of platelets, arterial thrombi appear white, whereas venous thrombi are red, reflecting the trapped red cells.

Antithrombotic drugs are used for prevention and treatment of thrombosis. Targeting the components of thrombi, these agents include (1) antiplatelet drugs, which inhibit platelets; (2) anticoagulants, which attenuate coagulation; and (3) fibrinolytic agents, which induce fibrin degradation (Fig. 151-1). With the predominance of platelets in arterial thrombi, strategies to inhibit or treat arterial thrombosis focus mainly on antiplatelet agents, although in the acute setting they often include anticoagulants and fibrinolytic agents. Anticoagulants are the mainstay of prevention and treatment of venous thromboembolism because fibrin is the predominant component of venous thrombi. Antiplatelet drugs are less effective than anticoagulants in this setting because of the limited platelet content of venous thrombi. Fibrinolytic therapy is used in selected patients with venous thromboembolism. For example, patients with massive or submassive pulmonary embolism can benefit from systemic or catheter-directed fibrinolytic therapy. Catheter-directed fibrinolytic therapy also can be used as an adjunct to anticoagulants for treatment of certain patients with extensive iliofemoral vein thrombosis.

This chapter focuses on antithrombotic agents. In addition to describing antiplatelet, anticoagulant, and fibrinolytic drugs that are in current use, new agents in advanced stages of development also are discussed.

ANTIPLATELET DRUGS

Role of Platelets in Arterial Thrombosis

In healthy vasculature, circulating platelets are maintained in an inactive state by nitric oxide and prostacyclin released by endothelial cells lining the blood vessels. In addition, endothelial cells also express ADPase on their surface, which degrades adenosine diphosphate (ADP) released from activated platelets (see Chapter 125). When the vessel wall is damaged, release of these substances is impaired and subendothelial matrix is exposed. Platelets adhere to exposed collagen and von Willebrand factor via $\alpha_2\beta_1$ and glycoprotein (GP) Ib-IX, respectively, receptors constitutively expressed on the platelet surface (see Chapter 127). Adherent platelets undergo a change in shape, secrete ADP from their dense granules, and synthesize and release thromboxane A_2. Released ADP and thromboxane A_2, which are platelet agonists, activate ambient platelets and recruit them to the site of vascular injury.

Disruption of the vessel wall also exposes tissue factor–expressing cells to the blood. Tissue factor initiates coagulation. Activated platelets potentiate coagulation by binding clotting factors and supporting the assembly of activation complexes that enhance thrombin generation. In addition to converting fibrinogen to fibrin, thrombin amplifies its own generation and serves as a potent platelet agonist, thereby recruiting additional platelets to the site of injury.

When platelets are activated, GPIIb/IIIa, the most abundant receptor on the platelet surface, undergoes a conformational change that enables it to ligate fibrinogen. Divalent fibrinogen molecules bridge adjacent platelets together to form platelet aggregates. Fibrin strands, generated through the action of thrombin, then weave these aggregates together to form a platelet/fibrin mesh.

Antiplatelet drugs target various steps in this process (Fig. 151-2). The commonly used drugs include aspirin, thienopyridines (ticlopidine, clopidogrel, and prasugrel), ticagrelor, dipyridamole, and GPIIb/IIIa antagonists. Each is briefly described.

Aspirin

The most widely used antiplatelet agent worldwide is aspirin. As a cheap and effective antiplatelet drug, aspirin serves as the foundation of most antiplatelet strategies.

Mechanism of Action

Aspirin produces its antithrombotic effect by irreversibly acetylating and inhibiting platelet cyclooxygenase (COX)-1, a critical enzyme in the biosynthesis of thromboxane A_2 (see Fig. 151-2). At high doses (about 1 g/day), aspirin also inhibits COX-2, an inducible COX isoform found in endothelial cells and inflammatory cells. In endothelial cells, COX-2 initiates the synthesis of prostacyclin, a potent vasodilator and inhibitor of platelet aggregation.

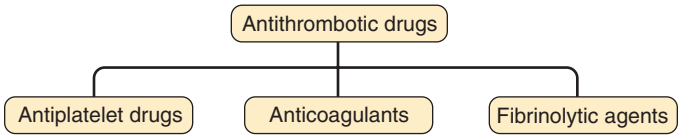

Figure 151-1 CLASSIFICATION OF ANTITHROMBOTIC DRUGS.

Indications

Aspirin is widely used for secondary prevention of cardiovascular events in patients with coronary artery disease, cerebrovascular disease, or peripheral vascular disease. Compared with placebo, aspirin produces about a 25% reduction in the risk for cardiovascular death, myocardial infarction, or stroke in these patients. There is controversy about the use of aspirin for primary prevention in subjects without clinical evidence of cardiovascular disease.[2] Although metaanalyses demonstrate a reduction in nonfatal myocardial infarction with daily aspirin use, this benefit is partially offset by an increase in gastrointestinal bleeding. Nonetheless, there also is evidence that aspirin reduces cancer mortality. If used for primary prevention, aspirin should be restricted to those at moderate to high risk for cardiovascular events.

Dosages

Aspirin is usually administered at doses of 75 to 325 mg once daily. There is no evidence that higher-dose aspirin is more effective than lower aspirin doses, and some analyses suggest reduced efficacy with higher doses. Because the side effects of aspirin are dose related, daily aspirin doses of 75 to 150 mg are recommended for most indications. When rapid platelet inhibition is required, an initial aspirin dose of at least 160 mg should be given.

Side Effects

Most common side effects are gastrointestinal and range from dyspepsia to erosive gastritis or peptic ulcers with associated bleeding. These side effects are, at least to some extent, dose related. Use of enteric-coated or buffered aspirin in place of plain aspirin does not eliminate the gastrointestinal side effects. The risk for major bleeding with aspirin ranges from 1% to 3% per year and is higher when aspirin is used in conjunction with anticoagulants, such as warfarin. When dual therapy is used, low-dose aspirin should be given (75 to 100 mg daily). Eradication of *Helicobacter pylori* infection and concomitant administration of proton pump inhibitors may reduce the risk for upper gastrointestinal bleeding, particularly in patients with a history of peptic ulcer disease.

Aspirin should not be administered to patients with aspirin allergy characterized by bronchospasm. This problem occurs in about 0.3% of the general population but is more common in those with chronic urticaria or asthma, particularly in subjects with coexisting nasal polyps or chronic rhinitis. Hepatic and renal toxicity are observed with aspirin overdose.

Aspirin Resistance

The term *aspirin resistance* has been used to describe both clinical and laboratory phenomena.[3] Clinical aspirin resistance is defined as the failure of aspirin to protect patients from ischemic vascular events. This is not a helpful definition because it is made after the event occurs. Furthermore, it is not realistic to expect aspirin, which only blocks thromboxane A_2–induced platelet activation, to prevent all vascular events.

Aspirin resistance also has been described biochemically as failure of the drug to produce its expected inhibitory effects on tests of platelet function, such as thromboxane A_2 synthesis or arachidonic acid–induced platelet aggregation. However, the tests used for the diagnosis of aspirin resistance are not well standardized. Furthermore, there is no definitive evidence that these tests identify patients at risk for recurrent vascular events, or that resistance can be reversed either by giving higher doses of aspirin or by adding other antiplatelet drugs. Until such information is available, testing for aspirin resistance remains a research tool.

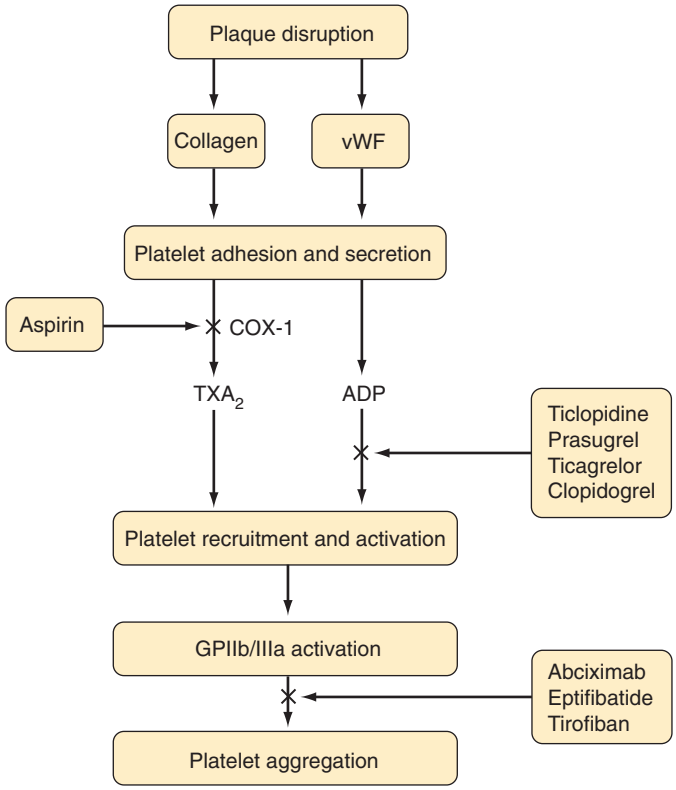

Figure 151-2 SITE OF ACTION OF ANTIPLATELET DRUGS. Aspirin inhibits thromboxane A_2 (TXA_2) synthesis by irreversibly acetylating cyclooxygenase-1 (COX-1). Reduced TXA_2 release attenuates platelet activation and recruitment to the site of vascular injury. Ticlopidine, clopidogrel, and prasugrel irreversibly block $P2Y_{12}$, a key adenosine diphosphate (ADP) receptor on the platelet surface whereas ticagrelor reversibly inhibits this receptor. Therefore these agents also attenuate platelet recruitment. Abciximab, eptifibatide, and tirofiban inhibit the final common pathway of platelet aggregation by blocking fibrinogen binding to activated glycoprotein (GP) IIb/IIIa. *vWF,* von Willebrand factor.

Thienopyridines

The thienopyridines include ticlopidine, clopidogrel, and prasugrel, drugs that target $P2Y_{12}$, the major ADP receptor on platelets.

Mechanism of Action

The thienopyridines are structurally related drugs that selectively inhibit ADP-induced platelet aggregation by irreversibly blocking $P2Y_{12}$ (see Fig. 151-2). Ticlopidine, clopidogrel, and prasugrel are prodrugs that must be metabolized by the hepatic cytochrome P450 (CYP) enzyme system to acquire activity. Consequently their onset of action is delayed unless loading doses are given. The metabolic activation of prasugrel is more efficient than that of ticlopidine or clopidogrel. Consequently prasugrel produces more rapid, higher, and more uniform $P2Y_{12}$ blockade than the other thienopyridines.

Indications

Ticlopidine is more effective than placebo at reducing the risk for cardiovascular death, myocardial infarction, and stroke in patients with atherosclerotic disease. Because of its delayed onset of action, ticlopidine is not recommended for patients with acute myocardial infarction. Ticlopidine was used routinely as an adjunct to aspirin after coronary artery stenting and as an aspirin substitute in those intolerant to aspirin. Because it is more potent than ticlopidine and has a better safety profile, clopidogrel has replaced ticlopidine in most countries.

When compared with aspirin in patients with recent ischemic stroke, myocardial infarction, or peripheral arterial disease, clopidogrel reduced the risk for cardiovascular death, myocardial infarction, and stroke by 8.7%. Therefore, clopidogrel is more effective than aspirin but also is more expensive. In some patients, clopidogrel and aspirin are combined to capitalize on their capacity to block complementary pathways of platelet activation. For example, the combination of aspirin plus clopidogrel is recommended for at least 4 weeks after implantation of a bare metal stent in a coronary artery and for at least 1 year in those with a drug-eluting stent. Concerns about late in-stent thrombosis with drug-eluting stents have led some experts to recommend long-term use of clopidogrel plus aspirin for this indication (see Chapter 148).

The combination of clopidogrel and aspirin also is effective in patients with unstable angina. Thus in 12,562 such patients the risk for cardiovascular death, myocardial infarction, or stroke was 9.3% in those randomized to the combination of clopidogrel and aspirin and 11.4% in those given aspirin alone, a 20% relative risk reduction. However, combining clopidogrel with aspirin increases the risk for major bleeding to about 2% per year. This bleeding risk persists even if the daily dose of aspirin is 100 mg or less. Therefore the combination of clopidogrel and aspirin should be used only when there is a clear benefit. For example, this combination has not proven to be superior to clopidogrel alone in patients with acute ischemic stroke or to aspirin alone for primary prevention in those at risk for cardiovascular events.

When compared with clopidogrel in 13,608 patients with acute coronary syndromes undergoing percutaneous coronary interventions, prasugrel reduced the combined rate of cardiovascular death, myocardial infarction, or stroke from 12.1% to 9.9%, a decrease mainly driven by a reduction in nonfatal myocardial infarction. However, prasugrel increased the rate of major bleeding and fatal bleeding, particularly in patients over the age of 65 years, those weighing less than 60 kg, and in those with a history of stroke. Prasugrel should not be used in patients with these characteristics.

Dosing

Ticlopidine is given twice-daily at a dose of 250 mg, whereas clopidogrel is given once-daily at a dose of 75 mg. Because its onset of action is delayed for several days, loading doses of clopidogrel are given when rapid ADP receptor blockade is desired. For example, patients undergoing coronary artery stenting are often given a loading dose of 600 mg, which produces inhibition of ADP-induced platelet aggregation within 6 hours. Prasugrel is given as a loading dose of 60 mg followed by 10 mg once daily. Partial inhibition of ADP-induced platelet aggregation is evident within 1 hour of prasugrel administration.

Side Effects

The most common side effects of ticlopidine are gastrointestinal. More serious are the hematologic side effects, which include neutropenia, thrombocytopenia, and thrombotic thrombocytopenic purpura. These side effects usually occur within the first few months of starting treatment. Therefore blood counts must be carefully monitored when initiating therapy with ticlopidine. Gastrointestinal and hematologic side effects, other than bleeding, are rare with clopidogrel and prasugrel.

Clopidogrel Resistance

There is between-subject variability in the capacity of clopidogrel to inhibit ADP-induced platelet aggregation.[4] This variability reflects, at least in part, genetic polymorphisms in CYP2C19, which is involved in the metabolic activation of clopidogrel. For example, subjects with the loss-of-function CYP2C19*2 and CYP2C19*3 alleles exhibit decreased responsiveness to clopidogrel. These alleles are found in 2% of white, 4% of black and 14% of Asian racial groups. Based on these findings, it is possible that pharmacogenetic profiling and point-of-care devices that assess the extent of platelet inhibition may help to identify clopidogrel-resistant patients. Such patients may benefit from a switch to prasugrel, which produces more uniform inhibition of ADP-induced platelet aggregation, or to ticagrelor.

Ticagrelor

An orally active agent belonging to the cyclopentyl-triazolopyrimidine class, ticagrelor acts as a direct inhibitor of $P2Y_{12}$.

Mechanism of Action

Ticagrelor binds to $P2Y_{12}$, at a location distinct from the ADP binding site and blocks ADP-mediated receptor activation in a noncompetitive fashion, likely through an allosteric mechanism. Because it does not require metabolic activation, ticagrelor has a more rapid onset of action than clopidogrel or prasugrel.

Dosing

Ticagrelor is given as a 180-mg oral loading dose followed by 80 mg twice daily. Although the trial with ticagrelor was not designed to stratify outcomes by geographic regions, patients enrolled from North America did not have the same benefit as those from other countries. Based on post-hoc analysis, the only baseline covariate associated with this difference was the higher dose of aspirin used in the United States. Consequently it is recommended that when combined with aspirin, the daily aspirin dose should be less than 100 mg.

When compared with clopidogrel in 18,624 patients with acute coronary syndromes, ticagrelor reduced the rate of cardiovascular death, myocardial infarction, or stroke from 11.7% to 9.8%.[5] All-cause mortality was also reduced with ticagrelor compared with clopidogrel (4.5% and 5.9%, respectively; P <.001), but ticagrelor produced more major bleeding not related to bypass surgery (2.8% and 2.2%, respectively).[5]

An invasive strategy was planned for 72% of the 18,624 patients entered in the trial. In this subset, the primary composite end point occurred in 9.0% of patients randomized to ticagrelor and in 10.7% of those given clopidogrel, a 16% reduction.[6] Rates of major bleeding were similar with ticagrelor and clopidogrel (11.6% and 16.5%, respectively; P = .88). Therefore ticagrelor is superior to clopidogrel.

Indications

If cost is not an issue and patients are compliant with twice-daily dosing, ticagrelor is a reasonable alternative to clopidogrel in patients with acute coronary syndrome regardless of whether they have been managed medically or have undergone a percutaneous coronary intervention with stent insertion. For these indications, ticagrelor should be given for at least a year. It also is reasonable to use ticagrelor in

place of clopidogrel in patients with increased platelet reactivity on clopidogrel or in those who developed in-stent thrombosis despite clopidogrel therapy.

Side Effects

Ticagrelor produces dyspnea, which is usually mild and dose related, asymptomatic bradycardia with ventricular pauses, and a modest increase in the levels of uric acid. The mechanisms responsible for these side effects are unclear. One possible explanation relates to the capacity of ticagrelor to inhibit adenosine reuptake by erythrocytes, thereby increasing circulating levels of adenosine. In addition to explaining the dyspnea and the bradycardia, the resultant adenosine-induced vasodilation and increased myocardial perfusion could also endow ticagrelor with beneficial effects that are independent of $P2Y_{12}$ blockade.

Dipyridamole

A relatively weak antiplatelet agent on its own, an extended-release formulation of dipyridamole combined with low-dose aspirin, a preparation known as Aggrenox, is used for prevention of stroke in patients with transient ischemic attacks.

Mechanism of Action

By inhibiting phosphodiesterase, dipyridamole blocks the breakdown of cyclic adenosine monophosphate (cAMP). Increased levels of cAMP reduce intracellular calcium and inhibit platelet activation. Dipyridamole also blocks the uptake of adenosine by platelets and other cells. This produces a further increase in local cAMP levels because the platelet adenosine A_2 receptor is coupled to adenylate cyclase (Fig. 151-3).

Dosing

Aggrenox is given twice daily. Each capsule contains 200 mg of extended-release dipyridamole and 25 mg of aspirin.

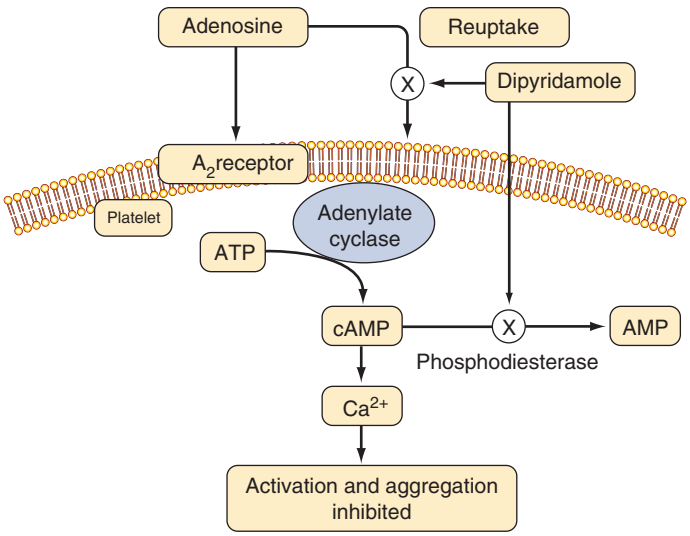

Figure 151-3 MECHANISM OF ACTION OF DIPYRIDAMOLE. Dipyridamole increases levels of cyclic adenosine monophosphate (cAMP) in platelets by (1) blocking the reuptake of adenosine and (2) inhibiting phosphodiesterase-mediated cAMP degradation. By promoting calcium uptake, cAMP reduces intracellular levels of calcium. This, in turn, inhibits platelet activation and aggregation. *AMP,* Adenosine monophosphate; *ATP,* adenosine triphosphate.

Side Effects

Because dipyridamole has vasodilatory effects, it must be used with caution in patients with coronary artery disease. Gastrointestinal complaints, headache, facial flushing, dizziness, and hypotension also can occur. These symptoms often subside with continued use of the drug.

Indications

Dipyridamole plus aspirin was compared with aspirin or dipyridamole alone, or with placebo, in patients with an ischemic stroke or transient ischemic attack. The combination reduced the risk for stroke by 22.1% compared with aspirin alone and by 24.4% compared with dipyridamole alone. A second trial compared dipyridamole plus aspirin with aspirin alone for secondary prevention in patients with ischemic stroke. Vascular death, stroke, or myocardial infarction occurred in 13% of patients given combination therapy and in 16% of those treated with aspirin alone. When Aggrenox was compared with clopidogrel, however, there was no difference in efficacy and there was more intracranial bleeding with Aggrenox.[7] Although Aggrenox is used for stroke prevention, because of its vasodilatory effects and the paucity of data supporting the use of dipyridamole in patients with symptomatic coronary artery disease, Aggrenox should not be used for stroke prevention in such patients (see Chapter 147).

GPIIb/IIIa Antagonists

As a class, parenteral GPIIb/IIIa antagonists have an established niche in patients with acute coronary syndromes. The three agents in this class are abciximab, eptifibatide, and tirofiban.

Mechanism of Action

A member of the integrin family of adhesion receptors, GPIIb/IIIa is found on the surface of platelets and megakaryocytes. With about 40,000 to 80,000 copies per platelet, GPIIb/IIIa is the most abundant receptor (see Chapter 127). Consisting of a noncovalently linked heterodimer, GPIIb/IIIa is inactive on resting platelets. When platelets are activated, inside-outside signal transduction pathways trigger a conformational activation of the receptor. Once activated, GPIIb/IIIa binds adhesive molecules, such as fibrinogen and, under high-shear conditions, von Willebrand factor. Binding is mediated by Arg-Gly-Asp (RGD) sequences found on the fibrinogen and von Willebrand factor and by the Lys-Gly-Asp (KGD) sequence located within a unique dodecapeptide domain on the γ-chains of fibrinogen. Once bound, fibrinogen and/or von Willebrand factor bridge adjacent platelets together to induce platelet aggregation.

Although abciximab, eptifibatide, and tirofiban all target the GPIIb/IIIa receptor, they are structurally and pharmacologically distinct (Table 151-1). Abciximab is a Fab fragment of a humanized murine monoclonal antibody directed against the activated form of GPIIb/IIIa. Abciximab binds to the activated receptor with high affinity and blocks the binding of adhesive molecules. In contrast to abciximab, eptifibatide and tirofiban are synthetic small molecules. Eptifibatide is a cyclic heptapeptide that binds GPIIb/IIIa because it incorporates the KGD motif, whereas tirofiban is a nonpeptidic tyrosine derivative that acts as an RGD mimetic. Abciximab has a long half-life and can be detected on the surface of platelets for up to 2 weeks. Eptifibatide and tirofiban have shorter half-lives.

In addition to targeting the GPIIb/IIIa receptor, abciximab also inhibits the closely related αvβ3 receptor, which binds vitronectin, and αMβ2, a leukocyte integrin. In contrast, eptifibatide and tirofiban are specific for GPIIb/IIIa. Inhibition of αvβ3 and αMβ2 may endow abciximab with antiinflammatory and/or antiproliferative properties that extend beyond platelet inhibition.

Table 151-1 Features of GPIIb/IIIa Antagonists

Feature	Abciximab	Eptifibatide	Tirofiban
Description	Fab fragment of humanized mouse monoclonal antibody	Cyclical KGD-containing heptapeptide	Nonpeptidic RGD mimetic
Specific for GPIIb/IIIa	No	Yes	Yes
Plasma half-life	Short (min)	Long (2.5 hr)	Long (2.0 hr)
Platelet-bound half-life	Long (days)	Short (sec)	Short (sec)
Renal clearance	No	Yes	Yes
Dosing	0.25-mg/kg bolus followed by a 12-hr infusion of 10 mcg/min	Two 180-mcg/kg boluses given 10 min apart	25-mcg/kg bolus followed by an18-hr infusion of 0.15 mcg/kg/min
Adjustment for renal impairment	No	Yes	Yes

KGD, Lys-Gly-Asp; *RGD,* Arg-Gly-Asp.

Dosing

All of the GPIIb/IIIa antagonists are given as an intravenous bolus followed by an infusion. Because they are cleared by the kidneys, the doses of eptifibatide and tirofiban must be reduced in patients with renal impairment.

Side Effects

In addition to bleeding, thrombocytopenia is the most serious complication (see Chapter 134). Thrombocytopenia is immune mediated and is caused by antibodies directed against neoantigens on GPIIb/IIIa that are exposed upon antagonist binding. With abciximab, thrombocytopenia occurs in up to 5% of patients. Thrombocytopenia is severe in about 1% of these individuals. Thrombocytopenia is less common with the other two agents, occurring in about 1% of treated patients.

Indications

These agents are used in patients undergoing percutaneous coronary interventions, particularly those with ST-segment elevation acute myocardial infarction. Tirofiban and eptifibatide are also used in high-risk patients with unstable angina.

New Antiplatelet Agents

Vorapaxar and atopaxar are orally active inhibitors of protease-activated receptor 1 (PAR1), the major thrombin receptor on platelets. Vorapaxar has been compared with placebo as an adjunct to standard of care in patients undergoing percutaneous coronary interventions[8] or for prevention of cardiovascular events in those with a history of stroke, myocardial infarction, or peripheral arterial disease.[9] Although vorapaxar shows promise for these indications, it causes excessive bleeding, including intracranial bleeding, in patients with a prior history of stroke, and its role has not yet been defined.

ANTICOAGULANTS

There are both parenteral and oral anticoagulants. Currently available parenteral anticoagulants include heparin, low-molecular-weight heparin (LMWH), and fondaparinux, a synthetic pentasaccharide. The oral anticoagulants include the vitamin K antagonists, of which warfarin is the agent most often used in North America, and new agents that target thrombin (dabigatran etexilate) or factor Xa (rivaroxaban and apixaban).[10]

Parenteral Anticoagulants

Heparin

A sulfated polysaccharide, heparin is isolated from mammalian tissues rich in mast cells. Most commercial heparin is derived from porcine intestinal mucosa and is a polymer of alternating D-glucuronic acid and N-acetyl-D-glucosamine residues.

Mechanism of Action

Heparin acts as an anticoagulant by activating antithrombin (previously known as antithrombin III) and accelerating the rate at which antithrombin inhibits clotting enzymes, particularly thrombin and factor Xa (see Chapter 128). Antithrombin, the obligatory plasma cofactor for heparin, is a 58,000-Da single-chain polypeptide that is a member of the serine protease inhibitor (serpin) superfamily. Synthesized in the liver and circulating in plasma at a concentration of 2.6 ± 0.4 μM, antithrombin acts as a suicide substrate for its target enzymes.

To activate antithrombin, heparin binds to the serpin via a unique pentasaccharide sequence that is found on one-third of the chains of commercial heparin (Fig. 151-4). The remainder of the heparin chains that lack this pentasaccharide sequence have little or no anticoagulant activity. Once bound to antithrombin, heparin induces a conformational change in the reactive center loop of antithrombin that renders it more readily accessible to its target proteases. This conformational change enhances the rate at which antithrombin inhibits factor Xa by at least two orders of magnitude but has little effect on the rate of thrombin inhibition by antithrombin. To catalyze thrombin inhibition, heparin serves as a template that binds antithrombin and thrombin simultaneously. Formation of this ternary complex brings the enzyme in close apposition to the inhibitor, thereby promoting the formation of a stable covalent thrombin-antithrombin complex.

Only pentasaccharide-containing heparin chains composed of at least 18 saccharide units (which correspond to a molecular weight of 5400) are of sufficient length to bridge thrombin and antithrombin together. With a mean molecular weight of 15,000, and a range of 5000 to 30,000, almost all of the chains of unfractionated heparin are long enough to affect this bridging function. Consequently, by definition, heparin has equal capacity to promote the inhibition of thrombin and factor Xa by antithrombin and is assigned an anti–factor Xa to anti–factor IIa (thrombin) ratio of 1 : 1 (Fig. 151-5).

In addition to activating antithrombin, heparin also can catalyze heparin cofactor II. This 66,000-Da serpin, which is found in plasma at a concentration of 1.2 ± 0.4 μM, is a specific inhibitor of thrombin. Two features account for the specificity of heparin cofactor II. First, the reactive site of heparin cofactor II contains the sequence

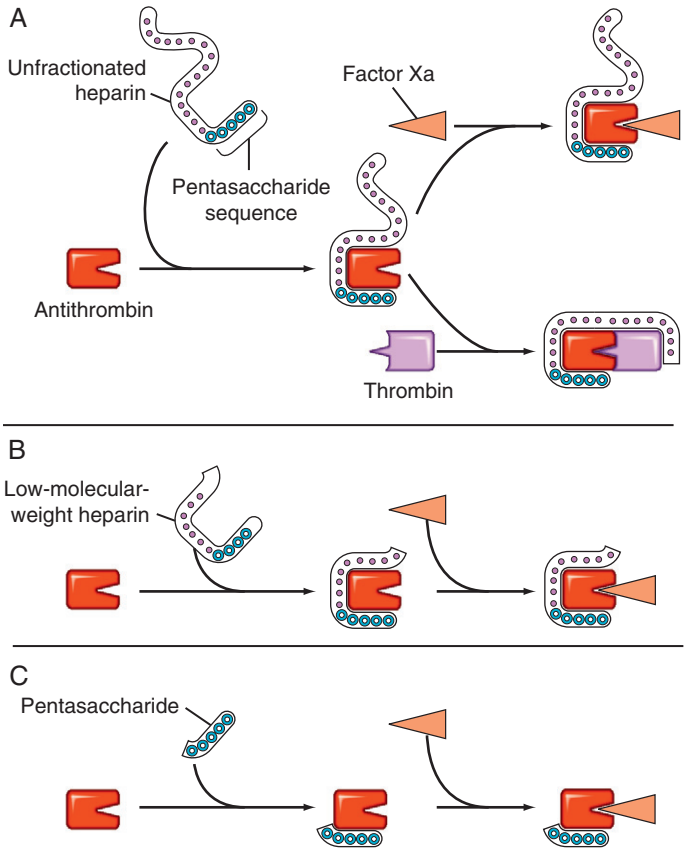

Figure 151-4 MECHANISM OF ACTION OF HEPARIN, LOW-MOLECULAR-WEIGHT HEPARIN (LMWH), AND FONDAPARINUX, A SYNTHETIC PENTASACCHARIDE. **A,** Heparin binds to antithrombin via its pentasaccharide sequence. This induces a conformational change in the reactive center loop of antithrombin that accelerates its interaction with factor Xa. To potentiate thrombin inhibition, heparin must simultaneously bind to antithrombin and thrombin. Only heparin chains composed of at least 18 saccharide units, which corresponds to a molecular weight of 5400, are of sufficient length to perform this bridging function. With a mean molecular weight of 15,000, all of the heparin chains are long enough to do this. **B,** LMWH has greater capacity to potentiate factor Xa inhibition by antithrombin than thrombin because, with a mean molecular weight of 4500 to 5000, at least half of the LMWH chains are too short to bridge antithrombin to thrombin. **C,** The pentasaccharide only accelerates factor Xa inhibition by antithrombin because the pentasaccharide is too short to bridge antithrombin to thrombin.

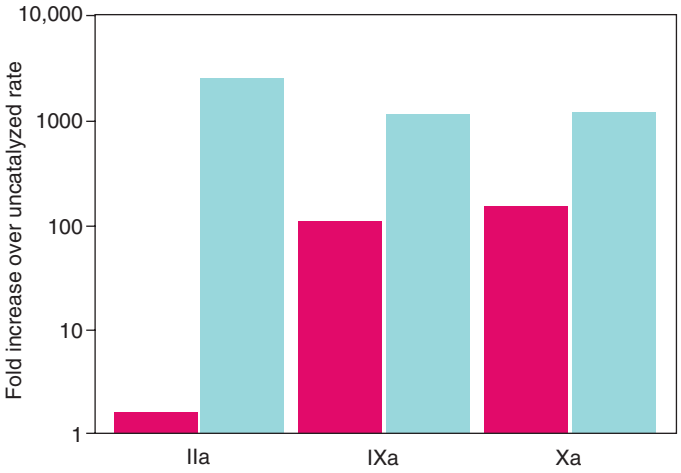

Figure 151-5 COMPARISON OF THE STIMULATORY EFFECTS OF PENTASACCHARIDE AND UNFRACTIONATED HEPARIN ON CATALYSIS OF ANTITHROMBIN-MEDIATED INHIBITION OF THROMBIN (IIa), FACTOR IXA (IXa), AND FACTOR XA (Xa). Second-order rate constants of inhibition of IIa, IXa, or Xa by antithrombin, measured in the presence of heparin *(green bars)* or fondaparinux *(pink bars),* were divided by those determined in the absence of glycosaminoglycan and are plotted as fold increase over the uncatalyzed rate of inhibition. *(Reprinted with permission from Wiebe EM, Stafford AR, Fredenburgh JC, et al: Mechanism of catalysis of inhibition of factor IXa by antithrombin in the presence of heparin or pentasaccharide,* J Biol Chem *278:35767, 2003.)*

Leu444-Ser445, a peptide bond that is not readily susceptible to cleavage by coagulation proteases other than thrombin. Second, heparin cofactor II possesses a unique anionic sequence at its N-terminal. In its unactivated state, this sequence forms an intramolecular bond with the positively charged glycosaminoglycan binding site located on the body of heparin cofactor II. When heparin or dermatan sulfate, a glycosaminoglycan that interacts only with heparin cofactor II, binds to heparin cofactor II, this N-terminal sequence is displaced, which enables its tethering to a positively charged domain on thrombin known as exosite 1. This tethering interaction occurs only with thrombin and facilitates thrombin inhibition by heparin cofactor II (Fig. 151-6).

Maximum catalysis of heparin cofactor II by heparin requires heparin chains composed of at least 26 saccharide units, which corresponds to a molecular weight of 7800. Longer heparin chains activate heparin cofactor II to a greater extent than shorter chains because the longer chains are of sufficient length to not only bind to heparin cofactor II, but to also bind to thrombin to form a ternary complex. Formation of this complex brings thrombin and heparin cofactor II into close apposition.

The interaction of heparin with heparin cofactor II is not mediated by the antithrombin-binding pentasaccharide sequence. Because heparin lacks a specific heparin cofactor II binding domain, heparin's affinity for heparin cofactor II is lower than that for antithrombin. Consequently 10-fold higher heparin concentrations are needed to accelerate thrombin inhibition by heparin cofactor II in plasma than are necessary to enhance thrombin's inactivation by antithrombin. Therefore it is likely that heparin cofactor II only contributes to the anticoagulant activity of heparin when the drug is given in high doses.

Heparin causes the release of tissue factor pathway inhibitor (TFPI) from the endothelium (see Chapters 128 and 129). A factor Xa–dependent inhibitor of tissue factor–bound factor VIIa, TFPI may contribute to the antithrombotic activity of heparin. Longer heparin chains induce the release of more TFPI than shorter chains.

Pharmacology

Heparin must be given parenterally. It is usually administered subcutaneously or by continuous intravenous infusion. When used for therapeutic purposes, the intravenous route is most often employed. If heparin is given subcutaneously for treatment of thrombosis, the dose of heparin must be high enough to overcome the limited bioavailability associated with this method of delivery.

After entering the circulation, heparin binds to a variety of plasma proteins other than antithrombin, which decreases the anticoagulant activity of heparin. The levels of heparin-binding proteins vary between patients because some of these proteins are acute-phase reactants whose levels are elevated in ill patients, whereas others, such as high-molecular-weight multimers of von Willebrand factor, are released when platelets or endothelial cells are activated by thrombin. Activated platelets also release platelet factor 4 (PF4), a highly cationic protein that binds heparin with high affinity. The large amount of PF4 found in the vicinity of platelet-rich arterial thrombi has the potential to locally neutralize the anticoagulant activity of heparin.

Because the levels of heparin-binding proteins are so variable between patients, the anticoagulant response to fixed or weight-adjusted doses of heparin is unpredictable. Consequently coagulation monitoring is essential to ensure that a therapeutic response is obtained when heparin is administered for treatment purposes.

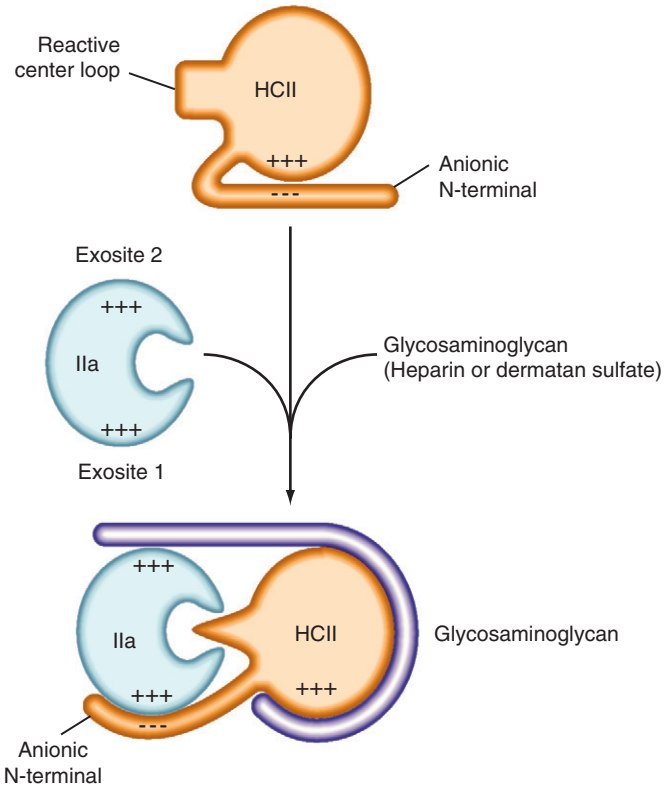

Figure 151-6 CATALYSIS OF HEPARIN COFACTOR II (HCII) BY GLYCOSAMINOGLYCANS. In its unactivated form, the acidic N-terminal tail of HCII is tethered to the positively charged glycosaminoglycan-binding site on the body of the serine protease inhibitor (serpin). The binding of heparin or dermatan sulfate to this binding site displaces the N-terminal tail, thereby facilitating the interaction of this anionic domain with exosite 1 on thrombin. Glycosaminoglycan binding also evokes a conformational change in the reactive center loop of HCII that contributes to the formation of the HCII-thrombin complex. Longer heparin chains not only bind to HCII, but also bind to the heparin-binding domain on thrombin, so-called exosite 2. Heparin-mediated bridging of HCII to thrombin enhances the rate of inhibition. Consequently, longer heparin chains that contain at least 26 saccharide units promote thrombin inhibition by HCII to a greater extent than shorter chains. Unlike heparin, dermatan sulfate does not need to bind to thrombin for maximal enhancement in the rate of thrombin inhibition because shorter dermatan sulfate fragments are just as active as longer ones.

Heparin is cleared through a combination of a rapid saturable and a much slower first-order mechanism. The saturable phase of heparin clearance is thought to be due to binding to endothelial cell receptors and macrophages. Bound heparin is internalized and depolymerized. The slower nonsaturable mechanism of clearance is largely renal. At therapeutic doses, a large proportion of heparin is cleared through the rapid saturable, dose-dependent mechanism. The complex kinetics of clearance make the anticoagulant response to heparin nonlinear at therapeutic doses, with both the intensity and duration of effect rising disproportionately with increasing dose. Thus the apparent biologic half-life of heparin increases from approximately 30 minutes after an intravenous bolus of 25 units/kg, to 60 minutes with an intravenous bolus of 100 units/kg, to 150 minutes with a bolus of 400 units/kg.

Monitoring

Heparin therapy can be monitored using the activated partial thromboplastin time (aPTT) or anti–factor Xa level. Although the aPTT is the test most often employed for this purpose, there are problems with this assay. aPTT reagents vary in their sensitivity to heparin, and the type of coagulometer used for testing can influence the results. Consequently laboratories must establish a therapeutic aPTT range with each reagent-coagulometer combination by measuring the aPTT and anti–factor Xa level in plasma samples collected from heparin-treated patients. For most of the aPTT reagents and coagulometers in current use, therapeutic heparin levels are achieved with a twofold to threefold prolongation of the aPTT.

Anti–factor Xa levels also can be used to monitor heparin therapy. With this test, therapeutic heparin levels range from 0.3 to 0.7 units/mL. Although this test is gaining in popularity, anti–factor Xa assays have yet to be standardized, and results can vary widely between laboratories.

Up to 25% of heparin-treated patients with venous thromboembolism require more than 35,000 units/day to achieve a therapeutic aPTT. These patients are considered heparin resistant. It is useful to measure anti–factor Xa levels in these patients because many will have a therapeutic anti–factor Xa level despite a subtherapeutic aPTT. This dissociation in test results occurs because elevated plasma levels of fibrinogen and factor VIII, both of which are acute-phase proteins, shorten the aPTT but have no effect on anti–factor Xa levels. Heparin therapy in patients who exhibit this phenomenon is best monitored using anti–factor Xa levels instead of the aPTT. Patients with congenital or acquired antithrombin deficiency and those with unusually high levels of heparin-binding proteins often require very high doses of heparin to achieve a therapeutic aPTT or anti–factor Xa level. If there is good correlation between the aPTT and the anti–factor Xa levels, either test can be used to monitor heparin therapy.

Dosing

For prophylaxis, heparin is usually given in fixed doses of 5000 units subcutaneously two or three times daily. With these low doses, coagulation monitoring is unnecessary. In contrast, monitoring is essential when heparin is given in therapeutic doses because a subtherapeutic anticoagulant response has been associated with a higher risk for recurrent thrombosis. Fixed-dose or weight-based heparin nomograms are used to standardize heparin dosing and to shorten the time required to achieve a therapeutic anticoagulant response. At least two heparin nomograms have been validated in patients with venous thromboembolism and reduce the time required to achieve a therapeutic aPTT. Weight-adjusted heparin nomograms also have been evaluated in patients with acute coronary syndromes.

Unmonitored twice-daily subcutaneous heparin proved as effective and safe as once-daily LMWH for initial treatment of venous thromboembolism in one study. High doses of heparin were used; treatment was started with a dose of 333 units/kg followed by 250 units/kg twice daily thereafter. This regimen may be an option for patients with renal insufficiency where LMWH or fondaparinux is problematic.

Limitations

Heparin has pharmacokinetic and biophysical limitations (Table 151-2). The pharmacokinetic limitations reflect heparin's propensity to bind in a pentasaccharide-independent fashion to cells and plasma proteins. Heparin binding to cells explains its dose-dependent clearance, whereas binding to plasma proteins results in a variable anticoagulant response and can lead to heparin resistance.

The biophysical limitations of heparin reflect the inability of the heparin-antithrombin complex to (1) inhibit factor Xa when it is incorporated into the prothrombinase complex, the complex that converts prothrombin to thrombin, and (2) to inhibit thrombin bound to fibrin. Consequently factor Xa bound to activated platelets within platelet-rich thrombi has the potential to generate thrombin, even in the face of heparin. Once this thrombin binds to fibrin, it too is protected from inhibition by the heparin-antithrombin complex. Clot-associated thrombin can then trigger thrombus growth by locally activating platelets and amplifying its own generation through feedback activation of factors V, VIII, and XI. Further

Table 151-2 Pharmacokinetic and Biophysical Limitations of Heparin

Limitations	Mechanism
Poor bioavailability at low doses	Limited absorption of long heparin chains
Dose-dependent clearance	Binds to endothelial cells
Variable anticoagulant response	Binds to plasma proteins whose levels vary from patient to patient
Reduced activity in the vicinity of platelet-rich thrombi	Neutralized by platelet factor 4 released from activated platelets within platelet-rich thrombi
Limited activity against factor Xa incorporated in the prothrombinase complex and thrombin bound to fibrin	Reduced capacity of heparin-antithrombin complex to inhibit factor Xa bound to activated platelets and thrombin bound to fibrin

Table 151-3 Features of Heparin-Induced Thrombocytopenia

Features	Details
Thrombocytopenia	Platelet count of 100,000/μL or less or a decrease in platelet count of 50% or more
Timing	Platelet count falls 5-10 days after starting heparin
Type of heparin	More common with unfractionated heparin than low-molecular-weight heparin
Type of patient	More common in surgical patients than medical patients. More common in women than in men
Thrombosis	Venous thrombosis more common than arterial thrombosis

Table 151-4 Management of Heparin-Induced Thrombocytopenia

Stop all heparin.
Give an alternative anticoagulant, such as lepirudin, argatroban, bivalirudin, danaparoid, or fondaparinux.
Do not give platelet transfusions.
Do not give warfarin until the platelet count returns to its baseline level. If warfarin is administered, give vitamin K to restore the INR to normal.
Evaluate for thrombosis, particularly deep venous thrombosis.

INR, International normalized ratio.

compounding the problem is the potential for heparin neutralization by the high concentrations of PF4 released from activated platelets within the platelet-rich thrombus.

Side Effects

The most common side effect of heparin is bleeding. Other complications include thrombocytopenia, osteoporosis, and elevated levels of transaminases.

Bleeding

The risk for heparin-induced bleeding increases with higher heparin doses. Concomitant administration of drugs that affect hemostasis, such as antiplatelet or fibrinolytic agents, increases the risk for bleeding, as does recent surgery or trauma. Heparin-treated patients with serious bleeding can be given protamine sulfate to neutralize the heparin. Protamine sulfate, a mixture of basic polypeptides isolated from salmon sperm, binds heparin with high affinity, and the resultant protamine-heparin complexes are then cleared. Typically 1 mg of protamine sulfate neutralizes 100 units of heparin. Protamine sulfate is given intravenously. Anaphylactoid reactions to protamine sulfate can occur, and drug administration by slow intravenous infusion is recommended to reduce the risk for these problems.

Thrombocytopenia

Heparin can cause thrombocytopenia. Heparin-induced thrombocytopenia (HIT) is an antibody-mediated process that is triggered by antibodies directed against neoantigens on PF4 that are exposed when heparin binds to this protein (see Chapter 135). These antibodies, which usually are of the immunoglobulin G (IgG) subtype, bind simultaneously to the heparin-PF4 complex and to platelet Fc receptors. Such binding activates the platelets and generates platelet microparticles. Circulating microparticles are prothrombotic because they express anionic phospholipids on their surface and can bind clotting factors, thereby promoting thrombin generation.

HIT can be associated with thrombosis, either arterial or venous (Table 151-3). Venous thrombosis, which manifests as deep venous thrombosis and/or pulmonary embolism, is more common than arterial thrombosis. Arterial thrombosis can manifest as ischemic stroke or acute myocardial infarction. Rarely, platelet-rich thrombi in the distal aorta or iliac arteries can cause critical limb ischemia.

The diagnosis of HIT is established using enzyme-linked assays to detect antibodies against heparin-PF4 complexes or with platelet activation assays. Enzyme-linked assays are sensitive but can be positive in the absence of any clinical evidence of HIT. The most specific diagnostic test is the serotonin-release assay. This test is performed by quantifying serotonin release when washed platelets loaded with labeled serotonin are exposed to patient serum in the absence or presence of varying concentrations of heparin. If the patient serum contains the HIT antibody, heparin addition induces platelet activation and subsequent serotonin release.

Management of HIT is outlined in Table 151-4. Heparin should be stopped in patients with suspected or documented HIT, and an alternative anticoagulant should be administered to prevent or treat thrombosis.[11] The agents most often used for this indication are parenteral direct thrombin inhibitors, such as lepirudin, argatroban, or bivalirudin, or factor Xa inhibitors, such as fondaparinux or danaparoid (see Chapter 135).

Patients with HIT, particularly those with associated thrombosis, often have evidence of increased thrombin generation that can lead to consumption of protein C. If these patients are given warfarin without a concomitant parenteral anticoagulant to suppress thrombin generation, the further decrease in protein C levels induced by warfarin can trigger skin necrosis. To avoid this problem, patients with HIT should be treated with a direct thrombin inhibitor or fondaparinux until the platelet count returns to normal levels. At this point, low-dose warfarin therapy can be introduced, and the thrombin inhibitor or fondaparinux can be discontinued when the anticoagulant response to warfarin has been therapeutic for at least 2 days.

Osteoporosis

Treatment with therapeutic doses of heparin for over a month can cause a reduction in bone density. This complication has been reported in up to 30% of patients given long-term heparin therapy, and symptomatic vertebral fractures occur in 2% to 3% of these individuals.

Studies in vitro and in laboratory animals have provided insights into the pathogenesis of heparin-induced osteoporosis. These investigations suggest that heparin causes bone resorption both by decreasing bone formation and by enhancing bone resorption. Thus heparin affects the activity of both osteoblasts and osteoclasts.

Elevated Levels of Transaminases

Therapeutic doses of heparin frequently cause modest elevation in the serum levels of hepatic transaminases, without a concomitant increase in the level of bilirubin. The levels of transaminases rapidly return to normal when the drug is stopped. The mechanism responsible for this phenomenon is unknown.

Low-Molecular-Weight Heparin

Consisting of smaller fragments of heparin, LMWH is prepared from unfractionated heparin by controlled enzymatic or chemical depolymerization. The mean molecular weight of LMWH is between 4500 and 5000, about one-third the mean molecular weight of unfractionated heparin. LMWH has advantages over heparin (Table 151-5) and has replaced heparin for most indications.

Mechanism of Action

Like heparin, LMWH exerts its anticoagulant activity by activating antithrombin. With a mean molecular weight of 4500 to 5000, which corresponds to about 17 saccharide units, at least half of the pentasaccharide-containing chains of LMWH are too short to bridge thrombin to antithrombin (see Fig. 151-4). However, these chains retain the capacity to accelerate factor Xa inhibition by antithrombin because this activity is largely the result of the conformational changes in antithrombin evoked by pentasaccharide binding. Consequently LMWH catalyzes factor Xa inhibition by antithrombin more than thrombin inhibition. Depending on their unique molecular weight distributions, LMWH preparations have anti–factor Xa to anti–factor IIa ratios ranging from 2:1 to 4:1.

Pharmacology

Although usually given subcutaneously, LMWH also can be administered intravenously if a rapid anticoagulant response is needed. LMWH has pharmacokinetic advantages over heparin. These advantages reflect the fact that shorter heparin chains bind less avidly to endothelial cells, macrophages, and heparin-binding plasma proteins. Reduced binding to endothelial cells and macrophages eliminates the rapid, dose-dependent, and saturable mechanism of clearance that is a characteristic of unfractionated heparin. Instead, the clearance of LMWH is dose independent, and its plasma half-life is longer. Based on measurement of anti–factor Xa levels, LMWH has a plasma half-life of about 4 hours. LMWH is cleared almost exclusively by the kidneys, and the drug can accumulate in patients with renal insufficiency.

LMWH exhibits about 90% bioavailability after subcutaneous injection. Because LMWH binds less avidly to heparin-binding proteins in plasma than heparin, LMWH produces a more predictable dose response and resistance to LMWH is rare. With a longer half-life and more predictable anticoagulant response, LMWH can be given subcutaneously once or twice daily without coagulation monitoring, even when the drug is given in treatment doses. These properties render LMWH more convenient than unfractionated heparin. Capitalizing on this feature, studies in patients with venous thromboembolism have shown that home treatment with LMWH is as effective and safe as in-hospital treatment with continuous intravenous infusions of heparin. Outpatient treatment with LMWH streamlines care, reduces health care costs, and increases patient satisfaction.

Table 151-5 Advantages of Low-Molecular-Weight Heparin Over Heparin

Advantage	Consequence
Better bioavailability and longer half-life after subcutaneous injection	Can be given subcutaneously once or twice daily for both prophylaxis and treatment
Dose-independent clearance	Simplified dosing
Predictable anticoagulant response	Coagulation monitoring is unnecessary in most patients
Lower risk for heparin-induced thrombocytopenia	Safer than heparin for short- or long-term administration
Lower risk for osteoporosis	Safer than heparin for extended administration

Monitoring

In the majority of patients, LMWH does not require coagulation monitoring. If monitoring is necessary, anti–factor Xa levels must be measured because most LMWH preparations have little effect on the aPTT. Therapeutic anti–factor Xa levels with LMWH range from 0.5 to 1.2 units/mL when measured 3 to 4 hours after drug administration. When LMWH is given in prophylactic doses, peak anti–factor Xa levels of 0.2 to 0.5 units/mL are desirable.

Indications for LMWH monitoring include renal insufficiency and morbid obesity. LMWH monitoring in patients with a creatinine clearance of 50 mL/min or less is advisable to ensure that there is no drug accumulation. Although weight-adjusted LMWH dosing appears to produce therapeutic anti–factor Xa levels in patients who are overweight, this approach has not been extensively evaluated in those with morbid obesity. It may also be advisable to monitor the anticoagulant activity of LMWH during pregnancy because dose requirements can change, particularly in the third trimester. Monitoring also is important in high-risk settings, such as in patients with mechanical mitral valves who are given LMWH for prevention of valve thrombosis.

Dosing

The doses of LMWH recommended for prophylaxis or treatment vary depending on the LMWH preparation. For prophylaxis, once-daily subcutaneous doses of 4000 to 5000 units are often used, whereas doses of 2500 to 3000 units are given when the drug is administered twice daily. For treatment of venous thromboembolism, a dose of 150 to 200 units/kg is given if the drug is administered once daily. If a twice-daily regimen is employed, a dose of 100 units/kg is given. In patients with unstable angina, LMWH is given subcutaneously on a twice-daily basis at a dose of 100 to 120 units/kg.

Side Effects

The major complication of LMWH is bleeding. Recent metaanalyses suggest that the risk for major bleeding may be lower with LMWH than with unfractionated heparin. HIT and osteoporosis are less common with LMWH than with unfractionated heparin.

Bleeding

Like the situation with heparin, bleeding with LMWH is more common in patients receiving concomitant therapy with antiplatelet or fibrinolytic drugs. Recent surgery, trauma, or underlying hemostatic defects also increase the risk for bleeding with LMWH.

Although protamine sulfate can be used as an antidote for LMWH, protamine sulfate incompletely neutralizes the anticoagulant activity of LMWH because it binds only the longer chains of LMWH. Because longer chains are responsible for catalysis of thrombin inhibition by antithrombin, protamine sulfate completely reverses the anti–factor IIa activity of LMWH. In contrast, protamine sulfate only partially reverses the anti–factor Xa activity of LMWH because the shorter pentasaccharide-containing chains of LMWH do not bind to protamine sulfate. Consequently patients at high risk for bleeding may be more safely treated with continuous intravenous unfractionated heparin than with subcutaneous LMWH. In addition to the potential for complete reversal with protamine sulfate, the short half-life of intravenous heparin also is an advantage if major bleeding occurs.

Thrombocytopenia

The risk for HIT is about fivefold lower with LMWH than with heparin. LMWH binds less avidly to platelets and causes less PF4 release. Furthermore, with lower affinity for PF4 than heparin, LMWH is less likely to induce the conformational changes in PF4 that trigger the formation of HIT antibodies.

LMWH should not be used to treat patients with HIT because most HIT antibodies exhibit cross-reactivity with LMWH and there are case reports of thrombosis when HIT patients were treated with LMWH (see Chapter 135).

Osteoporosis

The risk for osteoporosis is lower with long-term LMWH than with heparin. For extended treatment therefore LMWH is a better choice than heparin because of the lower risk for both osteoporosis and HIT.

Fondaparinux

A synthetic analogue of the antithrombin-binding pentasaccharide sequence, fondaparinux differs from LMWH in several ways (Table 151-6). Fondaparinux is licensed for (1) thromboprophylaxis in medical, general surgical, and high-risk orthopedic patients and (2) as an alternative to heparin or LMWH for initial treatment of patients with established venous thromboembolism. In some countries, fondaparinux also is approved as an alternative to heparin or LMWH for treatment of patients with acute coronary syndromes.

Mechanism of Action

As a synthetic analogue of the antithrombin-binding pentasaccharide sequence found in heparin and LMWH, fondaparinux has a molecular weight of 1728. Fondaparinux binds only to antithrombin (see Fig. 151-4) and is too short to bridge thrombin to antithrombin. Consequently fondaparinux catalyzes factor Xa inhibition by antithrombin and does not enhance the rate of thrombin inhibition.

Pharmacology

Fondaparinux exhibits complete bioavailability after subcutaneous injection. With no binding to endothelial cells or plasma proteins, the clearance of fondaparinux is dose independent and its plasma half-life is about 17 hours. The drug is given subcutaneously once daily. Because fondaparinux is cleared unchanged via the kidneys, it is contraindicated in patients with a creatinine clearance of less than 30 mL/min and it should be used with caution in those with a creatinine clearance of less than 50 mL/min.

Table 151-6 Comparison of Low-Molecular-Weight Heparin and Fondaparinux

Features	LMWH	Fondaparinux
Molecular weight	4500 to 5000	1728
Catalysis of factor Xa inhibition	Yes	Yes
Catalysis of thrombin inhibition	Yes	No
Bioavailability after subcutaneous administration (%)	90	100
Plasma half-life (hr)	4	17
Renal excretion	Yes	Yes
Induces release of tissue factor pathway inhibitor	Yes	No
Neutralized by protamine sulfate	Partially	No

LMWH, Low-molecular-weight heparin.

Fondaparinux produces a predictable anticoagulant response after administration in fixed doses because it does not bind to plasma proteins. The drug is given at a dose of 2.5 mg once daily for prevention of venous thromboembolism. For initial treatment of established venous thromboembolism, fondaparinux is given at a dose of 7.5 mg once daily. The dose can be reduced to 5 mg once daily for those weighing less than 50 kg and increased to 10 mg for those over 100 kg. When given in these doses, fondaparinux is as effective as heparin or LMWH for initial treatment of patients with deep venous thrombosis or pulmonary embolism and produces similar rates of bleeding.

Fondaparinux is used at a dose of 2.5 mg once daily in patients with acute coronary syndromes. When this prophylactic dose of fondaparinux was compared with treatment doses of enoxaparin in patients with non–ST segment elevation acute coronary syndromes, there was no difference in the rate of cardiovascular death, myocardial infarction, or stroke at 9 days.[12] However, the rate of major bleeding was 50% lower with fondaparinux than with enoxaparin, a difference that likely reflects the fact that the dose of fondaparinux was lower than that of enoxaparin. In acute coronary syndrome patients who require percutaneous coronary interventions, there is a risk for catheter thrombosis with fondaparinux unless adjunctive heparin is given.

Side Effects

Fondaparinux does not cause HIT, and, in contrast to LMWH, there is no cross-reactivity of fondaparinux with HIT antibodies. Interestingly, fondaparinux induces the formation of HIT antibodies to the same extent as LMWH. In contrast to heparin or LMWH, however, fondaparinux is too short to cluster PF4 tetramers together, which is a prerequisite for HIT antibody binding. This phenomenon not only explains why HIT antibodies do not cross-react with fondaparinux, but also explains why fondaparinux does not cause HIT despite the fact that it induces the formation of HIT antibodies. Although fondaparinux has been successfully used for HIT treatment, large clinical trials are lacking and the drug is not licensed for this indication.

The major side effect of fondaparinux is bleeding. There is no antidote for fondaparinux. Protamine sulfate has no effect on the anticoagulant activity of fondaparinux because it fails to bind to the drug. Recombinant activated factor VII reverses the anticoagulant effects of fondaparinux in volunteers, but it is unknown whether this agent will control fondaparinux-induced bleeding.

Parenteral Direct Thrombin Inhibitors

Heparin and LMWH are indirect inhibitors of thrombin because their activity is mediated by antithrombin. In contrast, direct thrombin inhibitors do not require a plasma cofactor; instead, these agents bind directly to thrombin and block its interaction with its substrates. Approved parenteral direct thrombin inhibitors include hirudin derivatives (lepirudin and desirudin), argatroban and bivalirudin (Table 151-7). Lepirudin and argatroban are licensed for treatment

Table 151-7 Comparison of the Properties of Hirudin, Bivalirudin, and Argatroban

	Hirudin	Bivalirudin	Argatroban
Molecular mass	7000	1980	527
Site(s) of interaction with thrombin	Active site and exosite 1	Active site and exosite 1	Active site
Renal clearance	Yes	No	No
Hepatic metabolism	No	No	Yes
Plasma half-life (min)	60	25	45

of patients with HIT, whereas bivalirudin is approved as an alternative to heparin in patients undergoing percutaneous coronary interventions, including those with HIT (see Chapter 135). Desirudin is licensed for thromboprophylaxis after elective hip replacement surgery.

Lepirudin and Desirudin

Recombinant forms of hirudin, lepirudin, and desirudin are bivalent direct thrombin inhibitors that interact with both the active site and exosite 1, the substrate binding site, on thrombin. Lepirudin is given by continuous intravenous infusion, whereas desirudin is administered subcutaneously twice daily. Lepirudin has a plasma half-life of 60 minutes after intravenous infusion, whereas the half-life of desirudin is about 2 hours. Both drugs are cleared by the kidneys and can accumulate in patients with renal insufficiency. A high proportion of lepirudin-treated patients develop antibodies against the drug. Although these antibodies rarely cause problems, in a small subset of patients they can delay lepirudin clearance and prolong its anticoagulant activity. Serious bleeding has been reported in some of these patients.

Desirudin is given subcutaneously in low doses and does not require monitoring. In contrast, lepirudin is usually monitored using the aPTT, and the dose is adjusted to maintain an aPTT that is 1.5 to 2.5 times the control. The aPTT is not an ideal test for monitoring lepirudin therapy because the clotting time plateaus with higher drug concentrations. Although the ecarin clotting time provides a better index of lepirudin dose than does the aPTT, the ecarin clotting time has yet to be standardized.

Argatroban

A univalent inhibitor that targets the active site of thrombin, argatroban is metabolized in the liver. Consequently this drug must be used with caution in patients with hepatic insufficiency. Argatroban is not cleared via the kidneys, so this drug is safer than lepirudin for HIT patients with renal insufficiency.

Argatroban is administered by continuous intravenous infusion and has a plasma half-life of about 45 minutes. The aPTT is used to monitor its anticoagulant effect, and the dose is adjusted to achieve an aPTT 1.5 to 3 times the baseline value, but not to exceed 100 seconds. Argatroban also prolongs the international normalized ratio (INR), a feature that can complicate the transitioning of patients from argatroban to warfarin. This problem can be circumvented by using the levels of factor X to monitor warfarin in place of the INR. Alternatively, the argatroban infusion can be stopped for 2 to 3 hours before INR determination.

Bivalirudin

A synthetic 20–amino acid analogue of hirudin, bivalirudin is a divalent thrombin inhibitor. Thus the N-terminal portion of bivalirudin interacts with the active site of thrombin, whereas its C-terminal tail binds to exosite 1. Bivalirudin has a plasma half-life of 25 minutes, the shortest half-life of all the parenteral direct thrombin inhibitors. Bivalirudin is degraded by peptidases and is partially excreted via the kidneys. When given in high doses in the cardiac catheterization laboratory, the anticoagulant activity of bivalirudin is monitored using the activated clotting time. With lower doses, its activity can be assessed using the aPTT.

Studies comparing bivalirudin with heparin plus GPIIb/IIIa antagonists suggest that bivalirudin produces less bleeding. This feature plus its short half-life make bivalirudin an attractive alternative to heparin in patients undergoing percutaneous coronary interventions, and it is licensed for this indication. Bivalirudin also is approved for management of HIT patients who require percutaneous coronary interventions (see Chapter 135).

ORAL ANTICOAGULANTS

Current oral anticoagulant practice dates back almost 60 years to when the vitamin K antagonists were discovered as a result of investigations into the cause of hemorrhagic disease in cattle. Characterized by a decrease in prothrombin levels, this disorder is caused by ingestion of hay containing spoiled sweet clover. Hydroxycoumarin, which was isolated from bacterial contaminants in the hay, interferes with vitamin K metabolism, thereby causing a syndrome similar to vitamin K deficiency. A variety of coumarin derivatives are available. The agent most widely used in North America is warfarin.

The repertoire of oral anticoagulants has expanded with the introduction of new oral anticoagulants that target thrombin or factor Xa.[10] These agents are now licensed for thromboprophylaxis after hip or knee replacement, stroke prevention in patients with atrial fibrillation, and, in some countries, for treatment of venous thrombosis. The drugs in this class include dabigatran, rivaroxaban, and apixaban.

Warfarin

A water-soluble vitamin K antagonist, warfarin was initially developed as a rodenticide. Like other vitamin K antagonists, warfarin interferes with the synthesis of the vitamin K–dependent clotting proteins, which include prothrombin (factor II) and factors VII, IX, and X. The synthesis of the vitamin K–dependent anticoagulant proteins, proteins C, S, and Z, also is reduced by vitamin K antagonists (see Chapter 128).

Mechanism of Action

All of the vitamin K–dependent clotting factors possess glutamic acid residues at their N-terminals. A posttranslational modification adds a carboxyl group to the γ-carbon of these residues to generate γ-carboxyglutamic acid (see Chapter 128). This modification is essential for expression of the activity of these clotting factors because it permits their calcium-dependent binding to negatively charged phospholipid surfaces. The γ-carboxylation process is catalyzed by a vitamin K–dependent carboxylase. Thus vitamin K from the diet is reduced to vitamin K hydroquinone by vitamin K reductase (Fig. 151-7). Vitamin K hydroquinone serves as a cofactor for the carboxylase enzyme, which in the presence of carbon dioxide replaces the hydrogen on the γ-carbon of glutamic acid residues with a carboxyl group. During this process, vitamin K hydroquinone is oxidized to vitamin K epoxide, which is then reduced to vitamin K by vitamin K epoxide reductase.

Warfarin inhibits vitamin K–epoxide reductase (VKOR), thereby blocking the γ-carboxylation process. This results in the synthesis of vitamin K–dependent clotting proteins that are only partially γ-carboxylated. Warfarin acts as an anticoagulant because these partially γ-carboxylated proteins have reduced or absent biologic activity. The onset of action of warfarin is delayed until the newly synthesized clotting factors with reduced activity gradually replace their fully active counterparts.

The antithrombotic effect of warfarin depends on a reduction in the functional levels of factor X and prothrombin, clotting factors that have half-lives of 24 and 72 hours, respectively. Because of the delay in achieving an antithrombotic effect, initial treatment with warfarin is supported by concomitant administration of a rapidly acting parenteral anticoagulant, such as heparin, LMWH, or fondaparinux, in patients with established thrombosis or at high risk for thrombosis.

Pharmacology

Warfarin is a racemic mixture of R and S isomers; of these, the S isomer is more active. Warfarin is rapidly and almost completely

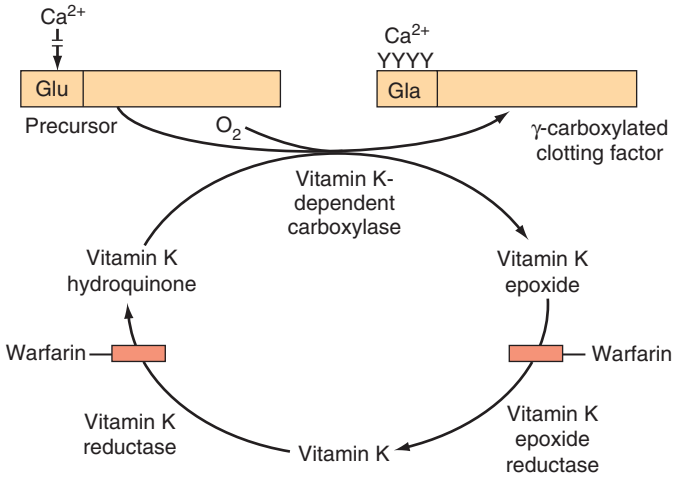

Figure 151-7 THE VITAMIN K CYCLE AND ITS INHIBITION BY WARFARIN. Dietary vitamin K is reduced by vitamin K reductase to generate vitamin K hydroquinone. Vitamin K hydroquinone serves as a cofactor for the vitamin K–dependent carboxylase that converts glutamic acid (Glu) residues at the N-terminals of the vitamin K–dependent precursors to γ-carboxyglutamic acid (Gla) residues, thereby creating the so-called Gla domain. By binding calcium, the Gla domain is critical for the interaction of the vitamin K–dependent clotting factors with negatively charged phospholipid membranes. During vitamin K–dependent carboxylation, vitamin K hydroquinone is oxidized to vitamin K epoxide. Vitamin K epoxide is then converted to vitamin K by vitamin K epoxide reductase. Vitamin K antagonists, such as warfarin, interfere with this cycle by inhibiting vitamin K epoxide reductase and vitamin K reductase. Of these two enzymes, vitamin K epoxide reductase is more readily blocked by vitamin K antagonists than vitamin K reductase. Consequently, supplemental vitamin K can overcome the inhibitory effects of vitamin K antagonists.

absorbed from the gastrointestinal tract. Levels of warfarin in the blood peak about 90 minutes after drug administration. Racemic warfarin has a plasma half-life of 36 to 42 hours, and over 97% of circulating warfarin is bound to albumin. It is only the small fraction of unbound warfarin that is biologically active.

Warfarin accumulates in the liver, where the two isomers are metabolized via distinct pathways. Oxidative metabolism of the more active S isomer is effected by CYP2C9.[13] Two relatively common variants, CYP2C9*2 and CYP2C9*3, have reduced activity. Patients with these variants require lower maintenance dose of warfarin. The target of warfarin is VKOR. Polymorphisms in the C1 subunit of this enzyme (VKORC1) also can render patients less or more responsive to the anticoagulant effects of warfarin.[13] These findings have prompted a recommendation that patients starting on warfarin should be tested for these polymorphisms and that this information should be incorporated into their warfarin-dosing algorithms. Whether this approach will increase the efficacy and/or safety of warfarin therapy is uncertain.

In addition to genetic factors, the anticoagulant effect of warfarin is influenced by diet, drugs, and various disease states. Fluctuations in dietary vitamin K intake affect the activity of warfarin. A wide variety of drugs can alter absorption, clearance, or metabolism of warfarin. Because of the variability in the anticoagulant response to warfarin, coagulation monitoring is essential to ensure that a therapeutic response is obtained.

Monitoring

Warfarin therapy is most often monitored using the prothrombin time, a test that is sensitive to reductions in the levels of prothrombin, factor VII, and factor X.[14] The test is performed by adding thromboplastin, a reagent that contains tissue factor, and phospholipid, and calcium to citrated plasma and determining the time to clot formation. Thromboplastins vary in their sensitivity to reductions in the levels of the vitamin K–dependent clotting factors. Consequently, less sensitive thromboplastins will prompt the administration of higher doses of warfarin to achieve a target prothrombin time. This is problematic because higher doses of warfarin increase the risk for bleeding.

The INR was developed to circumvent many of the problems associated with the prothrombin time assay (see Chapter 128). To calculate the INR, the patient's prothrombin time is divided by the mean normal prothrombin time and this ratio is then multiplied by the international sensitivity index (ISI), an index of the sensitivity of the thromboplastin used for prothrombin time determination to reductions in the levels of the vitamin K–dependent clotting factors. Highly sensitive thromboplastins have an ISI of 1.0. Most current thromboplastins have ISI values that range from 1.0 to 1.4.

Although the INR has helped to standardize anticoagulant practice, problems persist. The precision of INR determination varies depending on reagent-coagulometer combinations. This leads to variability in the INR results. Also complicating INR determination is unreliable reporting of the ISI by thromboplastin manufacturers. Furthermore, every laboratory must establish the mean normal prothrombin time with each new batch of thromboplastin reagent. To accomplish this, the prothrombin time must be measured in fresh plasma samples from at least 20 healthy volunteers using the same coagulometer that is used for patient samples.

For most indications, warfarin is administered in doses that produce a target INR of 2.0 to 3.0.[14] An exception is patients with mechanical heart valves, for whom a target INR of 2.5 to 3.5 is recommended.[14] Vitamin K antagonists have a narrow therapeutic window. Thus studies in atrial fibrillation demonstrate an increased risk for cardioembolic stroke when the INR falls below 1.7 and an increase in bleeding with INR values over 4.5. Likewise, a study in patients receiving long-term warfarin therapy for unprovoked venous thromboembolism demonstrated a higher rate of recurrent venous thromboembolism when the warfarin dose was adjusted to achieve a target INR of 1.5 to 1.9 than with a target INR of 2.0 to 3.0. Rates of major bleeding were similar.

Dosing

Warfarin is usually started at a dose of 5 to 10 mg. The dose is then titrated to achieve the desired target INR. Because of warfarin's delayed onset of action, patients with established thrombosis or those at high risk for thrombosis are given concomitant treatment with a rapidly acting parenteral anticoagulant, such as heparin, LMWH, or fondaparinux. Initial prolongation of the INR reflects reduction in the functional levels of factor VII. Consequently concomitant treatment with the parenteral anticoagulant should be continued until the INR has been therapeutic for at least 2 consecutive days. A minimum 5-day course of parenteral anticoagulation is recommended to ensure that the levels of prothrombin have been reduced into the therapeutic range with warfarin.

Because warfarin has a narrow therapeutic window, frequent coagulation monitoring is essential to ensure that a therapeutic anticoagulant response is obtained. Even patients with stable warfarin dose requirements should have their INR determined every 2 to 4 weeks.[14] More frequent monitoring is necessary when new medications are introduced because many drugs enhance or reduce the anticoagulant effects of warfarin.

Side Effects

The major side effect of warfarin, like all anticoagulants, is bleeding. A rare complication is skin necrosis. Warfarin crosses the placenta and can cause fetal abnormalities. Consequently warfarin should be avoided during pregnancy.

Bleeding

At least half of the bleeding complications with warfarin occur when the INR exceeds the therapeutic range. Bleeding complications may be mild, such as epistaxis or hematuria, or more severe, such as retroperitoneal or gastrointestinal bleeding. Life-threatening intracranial bleeding also can occur.

To minimize the risk for bleeding, the INR should be maintained in the therapeutic range. In asymptomatic patients whose INR is between 3.5 and 4.5, warfarin should be withheld until the INR returns to the therapeutic range. If the INR is over 4.5, a therapeutic INR can be achieved more rapidly by administration of low doses of sublingual vitamin K.

Patients with serious bleeding need more aggressive treatment. These patients should be given 5 to 10 mg of vitamin K by slow intravenous infusion. Additional vitamin K should be given until the INR is in the normal range. Treatment with vitamin K should be supplemented with fresh frozen plasma as a source of the vitamin K–dependent clotting proteins. For life-threatening bleeds, or if patients cannot tolerate the volume load, prothrombin complex concentrates can be used.[14]

Warfarin-treated patients who experience bleeding when their INR is in the therapeutic range require investigation into the cause of the bleeding. Those with gastrointestinal bleeding often have underlying peptic ulcer disease or a tumor. Similarly, investigation of hematuria or uterine bleeding in patients with a therapeutic INR may unmask a tumor of the genitourinary tract.

Skin Necrosis

A rare complication of warfarin, skin necrosis usually is seen 2 to 5 days after initiation of therapy. Well-demarcated erythematous lesions form on the thighs, buttocks, breasts, or toes. Typically the center of the lesion becomes progressively necrotic. Examination of skin biopsy specimens taken from the border of these lesions reveals thrombi in the microvasculature.

Warfarin-induced skin necrosis is seen in patients with congenital or acquired deficiencies of protein C or protein S (see Chapters 128, 129, and 142). Initiation of warfarin therapy in these patients produces a precipitous fall in plasma levels of proteins C or S, thereby eliminating this important anticoagulant pathway before warfarin exerts an antithrombotic effect through lowering of the functional levels of factor X and prothrombin. The resultant procoagulant state triggers thrombosis. Why the thrombosis is localized to the microvasculature of fatty tissues is unclear.

Treatment involves discontinuation of warfarin and reversal with vitamin K, if needed. An alternative anticoagulant, such as heparin or LMWH, should be given in patients with thrombosis. Protein C concentrates or recombinant activated protein C can be given to protein C–deficient patients to accelerate healing of the skin lesions; fresh frozen plasma may be of value for those with protein S deficiency. Occasionally skin grafting is necessary when there is extensive skin loss.

Because of the potential for skin necrosis, patients with known protein C or protein S deficiency require overlapping treatment with a parenteral anticoagulant when initiating warfarin therapy. Warfarin should be started in low doses in these patients, and the parenteral anticoagulant should be continued until the INR is therapeutic for at least 2 to 3 consecutive days.

Pregnancy

Warfarin crosses the placenta and can cause fetal abnormalities or bleeding. The fetal abnormalities include a characteristic embryopathy, which consists of nasal hypoplasia and stippled epiphyses. The risk for embryopathy is highest if warfarin is given in the first trimester of pregnancy. Central nervous system abnormalities also can occur with exposure to coumarins at any time during pregnancy. Finally, maternal administration of warfarin produces an anticoagulant effect in the fetus that can cause bleeding. This is of particular concern at delivery, when trauma to the head during passage through the birth canal can lead to intracranial bleeding. Because of these potential problems, warfarin is rarely used in pregnancy, particularly in the first and third trimesters. Instead, heparin, LMWH, or fondaparinux can be given during pregnancy for prevention or treatment of thrombosis.

Warfarin does not pass into the breast milk. Consequently warfarin can safely be administered to nursing mothers.

Special Problems

Patients with a lupus anticoagulant or those who need urgent or elective surgery present special challenges. Although observational studies suggested that patients with thrombosis complicating the antiphospholipid antibody syndrome required higher-intensity warfarin regimens to prevent recurrent thromboembolic events, two randomized trials demonstrated that targeting an INR of 2.0 to 3.0 is as effective as higher-intensity treatment and produces less bleeding. Monitoring warfarin therapy can be problematic in patients with antiphospholipid antibody syndrome if the lupus anticoagulant prolongs the baseline INR (see Chapter 143).

If patients receiving long-term warfarin treatment require an elective invasive procedure, warfarin can be stopped 5 days before the procedure to allow the INR to return to normal levels. Those at high risk for recurrent thrombosis can be bridged with once- or twice-daily subcutaneous injections of LMWH when the INR falls below 2.0. The last dose of LMWH should be given 12 to 24 hours before the procedure, depending on whether LMWH is administered twice or once daily, respectively. After the procedure, warfarin can be restarted.

Dabigatran

The active moiety of dabigatran etexilate, dabigatran targets the active site of thrombin and blocks its procoagulant activities. Dabigatran inhibits both free and fibrin-bound thrombin.

Mechanism of Action

Dabigatran etexilate is a prodrug with an oral bioavailability of 6% to 7%. Once absorbed, the drug is rapidly biotransformed by esterases to dabigatran, the levels of which peak 1 to 2 hours after oral administration. Dabigatran has a half-life of 14 to 17 hours. About 80% of the drug is excreted unchanged by the kidneys. Potent P-glycoprotein inhibitors, such as ketoconazole, are contraindicated.

Dosing

For thromboprophylaxis after hip or knee replacement surgery, dabigatran is given once daily at a dose of 220 or 150 mg; a half-dose is given on the day of surgery. In patients with atrial fibrillation, dabigatran is given at a dose of 150 mg or 110 mg twice daily. A dose of 75 mg twice daily is used in the United States for patients with a creatinine clearance of 15 to 30 mL/min, whereas the 150 mg twice-daily dose is recommended for those with a creatinine clearance over 30 mL/min; the 110-mg twice-daily dose is not licensed in the United States (see Chapters 147 and 149). For treatment of venous thromboembolism, dabigatran is given at a dose of 150 mg twice daily (see Chapter 144).

Side Effects

Dabigatran can be associated with dyspepsia. Taking the drug with food often helps to alleviate this problem. Compared with warfarin,

there may be a small increase in the risk for myocardial infarction with dabigatran. This increase translates into 2 additional myocardial infarcts for every 1000 patients treated. However, mortality appears to be lower with dabigatran.

There is no antidote for dabigatran. Unactivated prothrombin complex concentrates do not reverse the anticoagulant effects of dabigatran (i.e., prolongation of the aPTT or thrombin time) but attenuate dabigatran-induced bleeding in animal models. Unactivated or activated prothrombin complex concentrates or factor VIIa are reasonable choices in patients on dabigatran who have life-threatening bleeding.

Indications

In many countries, dabigatran is licensed for prophylaxis after hip or knee replacement surgery. Although not inferior to once-daily low-molecular-weight heparin for this indication, once-daily dabigatran was inferior to twice-daily low-molecular-weight heparin for thromboprophylaxis after elective knee replacement surgery.

At the 150-mg twice-daily dose, dabigatran was superior to warfarin for reduction in both hemorrhagic and ischemic stroke.[15] Rates of major and life-threatening bleeding were similar and lower, respectively, with dabigatran than with warfarin. In those over the age of 75 years, there is more gastrointestinal bleeding with this dose of dabigatran than with warfarin.[16]

When used at the 110-mg twice-daily dose, dabigatran is not inferior to warfarin for stroke prevention but is associated with significantly less intracranial and major bleeding.[15] In those over the age of 75 years, the rates of gastrointestinal bleeding with this dose of dabigatran and warfarin are similar.[16] The 75-mg twice-daily dose, which is only licensed in the United States, has not been tested in humans. However, the dose was selected because pharmacokinetic data revealed similar drug exposure in those with reduced renal function as produced by the 150-mg twice-daily dose in those with a creatinine clearance over 30 mL/min. Although drug exposure is similar, the half-life of dabigatran is prolonged to several days in those with impaired renal function.

For treatment of venous thromboembolism, dabigatran is not inferior to warfarin and is associated with reduced major plus clinically relevant nonmajor bleeding. Dabigatran is started after a 5- to 7-day course of heparin or low-molecular-weight heparin.[17]

Rivaroxaban

An oral factor Xa inhibitor, rivaroxaban is an active drug that targets the active site of factor Xa even when the enzyme is incorporated in the prothrombinase complex.

Mechanism of Action

Rivaroxaban has an oral bioavailability of 80%, and plasma levels peak 2 to 3 hours after drug administration. The terminal half-life is 7 to 11 hours, and one-third of the drug is cleared unchanged by the kidneys. The remainder is metabolized in the liver; half is cleared by the kidneys as inactive metabolites, and the rest is excreted in the feces. The pharmacokinetic and pharmacodynamic profile is dose dependent and is not influenced by age, gender, or body weight. Potent inhibitors of both P-glycoprotein and CYP3A4, such as ketoconazole or ritonavir, are contraindicated because they increase drug exposure.

Dosing

For thromboprophylaxis after hip or knee replacement surgery, rivaroxaban is given once daily at a dose of 10 mg.[18] When used for stroke prevention in atrial fibrillation, the dose is 20 mg once daily. The dose is reduced to 15 mg once daily for those with a creatinine clearance of 15 to 49 mL/min. For treatment of venous thromboembolism, rivaroxaban is started at a dose of 15 mg twice daily for 3 weeks and the dose is then reduced to 20 mg once daily thereafter. When used as an adjunct to antiplatelet therapy in stabilized patients with acute coronary syndrome, rivaroxaban is given at a dose of 2.5 mg twice daily.

Side Effects

Rivaroxaban is well tolerated and is not associated with dyspepsia or hepatic toxicity. The major side effect is bleeding. There is no specific antidote for rivaroxaban. Although prothrombin complex concentrate reverses the anticoagulant effects of rivaroxaban, its utility for treatment of bleeding is uncertain. Nonetheless, unactivated or activated prothrombin complex concentrate or factor VIIa should be considered in patients with life-threatening bleeding.

Indications

When used for thromboprophylaxis after hip or knee replacement surgery, the risk for major bleeding is similar to that with low-molecular-weight heparin.[18] Compared with warfarin for stroke prevention in atrial fibrillation, rivaroxaban is associated with less intracranial bleeding and hemorrhagic stroke, but similar rates of major bleeding (see Chapters 147 and 149).[19] In patients with acute venous thromboembolism, rivaroxaban is as effective as conventional anticoagulant therapy but is associated with less major bleeding (see Chapter 144).[20,21] When compared with placebo as an adjunct to antiplatelet therapy in stabilized patients with acute coronary syndromes, rivaroxaban (at a dose of 2.5 mg twice daily) reduced the primary efficacy end point—the composite of cardiovascular death, myocardial infarction, and stroke—from 10.7% to 9.1%.[22] There was more bleeding with rivaroxaban, including intracranial bleeding, but there was no increase in fatal bleeding.

Current licensed indications for rivaroxaban include (1) thromboprophylaxis after hip or knee replacement surgery, situations in which the drug is usually given for 2 and 4 weeks, respectively, and (2) as an alternative to warfarin for stroke prevention in atrial fibrillation. The drug also is licensed in some countries for treatment of deep venous thrombosis and is under consideration for treatment of pulmonary embolism and for secondary prevention in stabilized patients with acute coronary syndromes.

Apixaban

Another oral factor Xa inhibitor, apixaban is licensed in many countries, but not the United States, for thromboprophylaxis after hip or knee replacement surgery. It is under consideration for licensing as an alternative to aspirin or warfarin for stroke prevention in atrial fibrillation.

Mechanism of Action

Like rivaroxaban, apixaban targets the active site of free factor Xa or factor Xa incorporated in the prothrombinase complex. The drug has about 50% oral bioavailability, and plasma levels peak 3 to 4 hours after drug administration. The half-life of apixaban is 8 to 14 hours. Apixaban is metabolized in the liver via CYP3A4/5-dependent and independent pathways. About 25% of the drug is cleared unchanged by the kidneys, and the remainder is excreted in the feces. Potent inhibitors of CYP3A4/5 and P-glycoprotein increase drug exposure and should be avoided.

Dosing

Apixaban is given twice daily at a dose of 2.5 mg for thromboprophylaxis after hip or knee replacement surgery and at 5 mg for stroke prevention in patients with atrial fibrillation. For the latter indication, the dose is reduced to 2.5 mg twice daily in patients with impaired renal function.

Side Effects

Apixaban has excellent tolerability, and the rate of discontinuation due to adverse events is similar to or lower than that with aspirin. The drug does not cause dyspepsia and is not associated with hepatic toxicity. The major side effect is bleeding. Like the situation with dabigatran and rivaroxaban, there is no specific antidote for apixaban. Unactivated or activated prothrombin complex concentrates or factor VIIa may be of benefit in patients with life-threatening bleeding.

Indications

Although not licensed in the United States, apixaban is licensed in many countries for thromboprophylaxis after hip or knee replacement surgery. The drug is under consideration for licensing as an alternative to aspirin or warfarin for stroke prevention in patients with atrial fibrillation.

For thromboprophylaxis after hip or knee replacement surgery, apixaban has efficacy and safety similar to those of low-molecular-weight heparin.[23-25] Apixaban was superior to aspirin for stroke prevention in atrial fibrillation patients unwilling or unable to take warfarin and did not significantly increase the risk for bleeding.[26] When compared with warfarin for stroke prevention in patients with atrial fibrillation, apixaban produced a greater reduction in hemorrhagic stroke, but not ischemic stroke, and was associated with less major bleeding and lower all-cause mortality.[27]

Other New Oral Anticoagulants

Edoxaban and betrixaban are other oral factor Xa inhibitors under development. Edoxaban is being evaluated as an alternative to warfarin for stroke prevention in atrial fibrillation and for treatment of venous thromboembolism. Betrixaban has entered phase III evaluation for thromboprophylaxis in medically ill patients where it is being compared with low-molecular-weight heparin.

FIBRINOLYTIC DRUGS

Role of Fibrinolytic Therapy

Used to degrade thrombi, fibrinolytic drugs can be administered systemically, or they can be delivered via catheters directly into the substance of the thrombus (see Chapter 145). Systemic delivery is used for treatment of acute myocardial infarction (see Chapter 148), acute ischemic stroke (see Chapter 147), and most cases of massive pulmonary embolism (see Chapter 144). The goal of therapy is to produce rapid thrombus dissolution, thereby restoring antegrade blood flow. In the coronary circulation, restoration of blood flow reduces morbidity and mortality by limiting myocardial damage, whereas in the cerebral circulation, rapid thrombus dissolution decreases the neuronal death and brain infarction that produce irreversible brain injury. For patients with massive pulmonary embolism, the goal of fibrinolytic therapy is to restore pulmonary artery perfusion.

Peripheral arterial thrombi and thrombi in the proximal deep veins of the leg are most often treated using a catheter-directed approach. Catheters with multiple side holes can be used to deliver fibrinolytic drugs. In some cases, intravascular devices that fragment and extract the thrombus are used to hasten treatment (see Chapter 145).

Mechanism of Action

Commonly used fibrinolytic agents include streptokinase, recombinant tissue plasminogen activator (rt-PA), which is also known as *alteplase* (Activase), and two recombinant derivatives of rt-PA, tenecteplase and reteplase. All of these agents act by converting the proenzyme, plasminogen, to plasmin, the active enzyme (Fig. 151-8). Plasmin then degrades the fibrin matrix of thrombi, thereby producing soluble fibrin degradation products.

Endogenous fibrinolysis is regulated at two levels. Plasminogen activator inhibitors, particularly the type 1 form, known as PAI-1, prevent excessive plasminogen activation by regulating the activity of t-PA and urokinase plasminogen activator (uPA). Once plasmin is generated, it is regulated by plasmin inhibitors, the most important of which is α_2-antiplasmin. The plasma concentration of plasminogen is twofold higher than that of α_2-antiplasmin. Consequently with pharmacologic doses of plasminogen activators, the concentration of plasmin that is generated can exceed that of α_2-antiplasmin. In addition to degrading fibrin, unregulated plasmin also can degrade fibrinogen and other clotting factors. This process, which is known as the systemic lytic state, reduces the hemostatic potential of the blood and increases the risk for bleeding.

The endogenous fibrinolytic system is geared to localize plasmin generation to the fibrin surface. Both plasminogen and t-PA bind to fibrin to form a ternary complex that promotes efficient plasminogen activation. In contrast to free plasmin, plasmin generated on the fibrin surface is relatively protected from inactivation by α_2-antiplasmin, a feature that promotes fibrin dissolution. Furthermore, C-terminal lysine residues exposed as plasmin degrades fibrin serve as binding sites for additional plasminogen and t-PA molecules. This creates a positive feedback that enhances plasmin generation. When used pharmacologically, the various plasminogen activators capitalize on these mechanisms to a lesser or greater extent.

There are two pools of plasminogen: circulating plasminogen and fibrin-bound plasminogen (Fig. 151-9). Plasminogen activators that preferentially activate fibrin-bound plasminogen are considered fibrin specific. In contrast, nonspecific plasminogen activators do not discriminate between fibrin-bound and circulating plasminogen. Activation of circulating plasminogen results in the generation of unopposed plasmin that can trigger the systemic lytic state. Alteplase and its derivatives are fibrin-specific plasminogen activators, whereas streptokinase is a nonspecific agent.

Streptokinase

Unlike other plasminogen activators, streptokinase is not an enzyme and does not directly convert plasminogen to plasmin. Instead, streptokinase forms a 1 : 1 stoichiometric complex with plasminogen. Formation of this complex induces a conformational change in

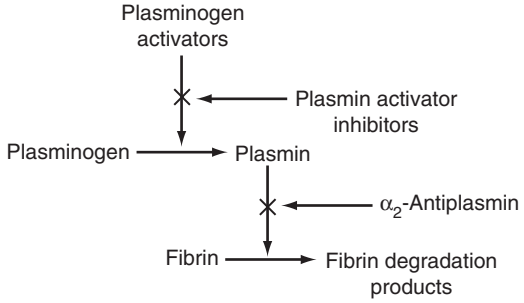

Figure 151-8 FIBRINOLYTIC SYSTEM AND ITS REGULATION. Plasminogen activators convert plasminogen to plasmin. Plasmin then degrades fibrin into soluble fibrin degradation products. The system is regulated at two levels. Type 1 plasminogen activator inhibitor (PAI-1) regulates the plasminogen activators, whereas α_2-antiplasmin serves as the major inhibitor of plasmin.

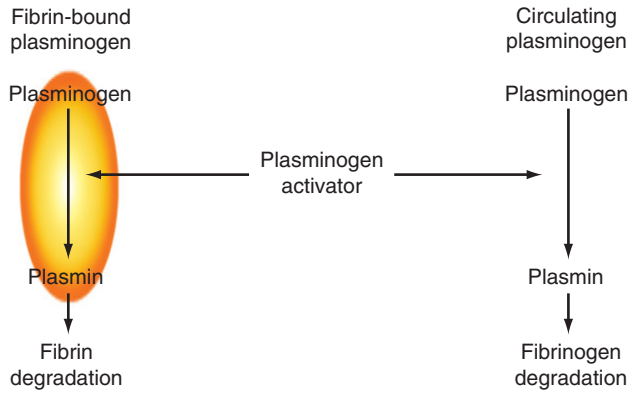

Figure 151-9 CONSEQUENCES OF ACTIVATION OF FIBRIN-BOUND OR CIRCULATING PLASMINOGEN. The fibrin specificity of plasminogen activators reflects their capacity to distinguish between fibrin-bound and circulating plasminogen. This, in turn, reflects their affinity for fibrin. Plasminogen activators with high affinity for fibrin preferentially activate fibrin-bound plasminogen. This results in the generation of plasmin on the fibrin surface. Fibrin-bound plasmin, which is protected from inactivation by α_2-antiplasmin, degrades fibrin to yield soluble fibrin degradation products. In contrast, plasminogen activators with little or no affinity for fibrin do not distinguish between fibrin-bound and circulating plasminogen. Activation of circulating plasminogen results in systemic plasminemia and subsequent degradation of fibrinogen and other clotting factors.

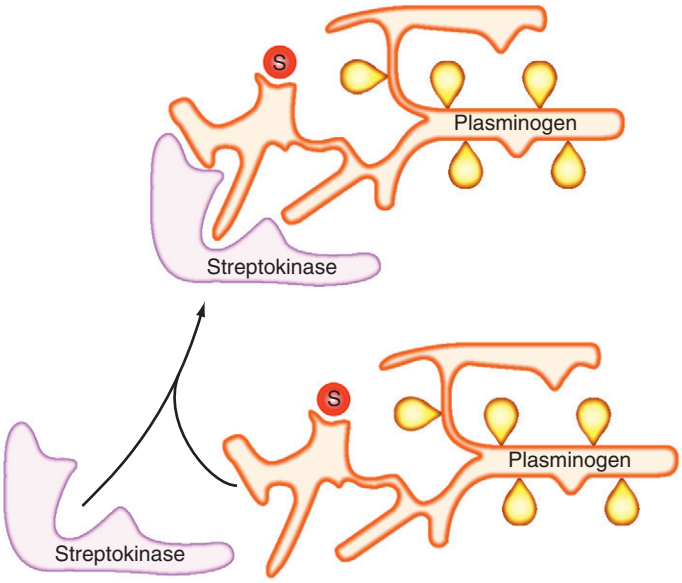

Figure 151-10 MECHANISM OF ACTION OF STREPTOKINASE. Streptokinase binds to plasminogen and induces a conformational change in plasminogen that exposes its active site serine (S). The streptokinase/plasmin(ogen) complex then serves as the activator of additional plasminogen molecules.

plasminogen that exposes its active site (Fig. 151-10). This conformationally altered plasminogen then converts additional plasminogen molecules to plasmin.

Streptokinase has no affinity for fibrin, and the streptokinase-plasminogen complex activates both free and fibrin-bound plasminogen. Activation of circulating plasminogen generates sufficient amounts of plasmin to overwhelm α_2-antiplasmin. Unopposed plasmin not only degrades fibrin in the occlusive thrombus but also induces a systemic lytic state.

When given systemically to patients with acute myocardial infarction, streptokinase reduces mortality. For this indication the drug is usually given as an intravenous infusion of 1.5 million units over 30

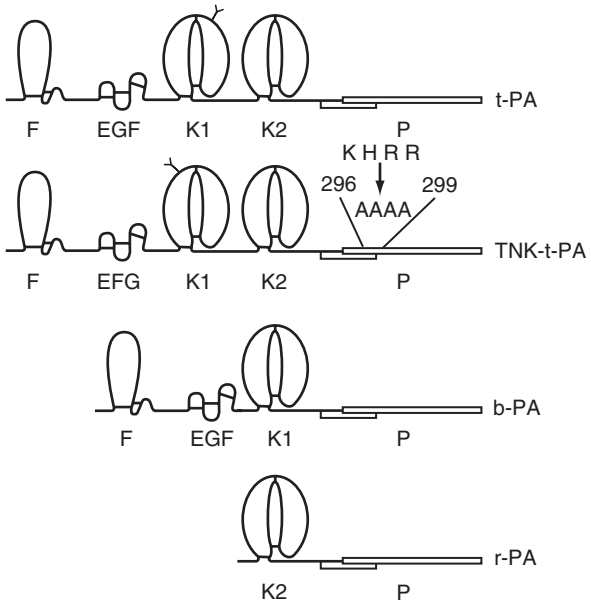

Figure 151-11 DOMAIN STRUCTURES OF ALTEPLASE (t-PA), TENECTEPLASE (TNK-t-PA), DESMOTEPLASE (b-PA), AND RETEPLASE (r-PA). The finger (F), epidermal growth factor (EGF), first and second kringles (K1 and K2, respectively), and protease (P) domains are illustrated. The glycosylation site (Y) on K1 has been repositioned in tenecteplase to endow it with a longer half-life. In addition, a tetraalanine substitution in the protease domain renders tenecteplase resistant to PAI-1 inhibition. Desmoteplase differs from alteplase and tenecteplase in that it lacks a K2 domain. Reteplase is a truncated variant that lacks the F, EGF, and K1 domains.

to 60 minutes. Patients who receive streptokinase can develop antibodies against the drug as can patients with prior streptococcal injection. These antibodies can reduce the effectiveness of streptokinase.

Allergic reactions occur in about 5% of patients treated with streptokinase. These may manifest as a rash, fever, chills, and rigors. Although anaphylactic reactions can occur, these are rare. Transient hypotension is common with streptokinase and has been attributed to plasmin-mediated release of bradykinin from kallikrein. The hypotension usually responds to leg elevation and administration of intravenous fluids and low-doses of vasopressors, such as dopamine or norepinephrine.

Alteplase

A recombinant form of single-chain t-PA, alteplase has a molecular weight of 68,000. Alteplase is rapidly converted into its two-chain form by plasmin. Although single- and two-chain forms of t-PA have equivalent activity in the presence of fibrin, in its absence, single-chain t-PA has 10-fold lower activity.

Alteplase consists of five discrete domains (Fig. 151-11). The N-terminal A-chain of two-chain alteplase contains four of these domains. Residues 4 to 50 make up the finger domain, a region that resembles the finger domain of fibronectin; residues 50 to 87 are homologous with epidermal growth factor; whereas residues 92 to 173 and 180 to 261, which have homology to the kringle domains of plasminogen, are designated as the first and second kringle, respectively. The fifth alteplase domain is the protease domain; it is located on the C-terminal B-chain of two-chain alteplase.

The interaction of alteplase with fibrin is mediated by the finger domain, and to a lesser extent by the second kringle domain. The affinity of alteplase for fibrin is considerably higher than that for fibrinogen. Consequently the catalytic efficiency of plasminogen activation by alteplase is two to three orders of magnitude higher in the presence of fibrin than in the presence of fibrinogen. This phenomenon helps to localize plasmin generation to the fibrin surface.

Although alteplase preferentially activates plasminogen in the presence of fibrin, alteplase is not as fibrin-selective as was first predicted. Its fibrin specificity is limited because like fibrin, (DD)E, the major soluble degradation product of cross-linked fibrin, binds alteplase and plasminogen with high affinity. Consequently, (DD)E is as potent as fibrin as a stimulator of plasminogen activation by alteplase. Whereas plasmin generated on the fibrin surface results in thrombolysis, plasmin generated on the surface of circulating (DD)E degrades fibrinogen. Fibrinogenolysis results in the accumulation of fragment X, a high-molecular-weight clottable fibrinogen degradation product. Incorporation of fragment X into hemostatic plugs formed at sites of vascular injury renders them susceptible to lysis. This phenomenon may contribute to alteplase-induced bleeding.

A trial comparing alteplase with streptokinase for treatment of patients with acute myocardial infarction demonstrated significantly lower mortality with alteplase than with streptokinase, although the absolute difference was small. The greatest benefit was seen in patients less than 75 years of age with anterior myocardial infarction who presented less than 6 hours after symptom onset.

For treatment of acute myocardial infarction or acute ischemic stroke, alteplase is given as an intravenous infusion over 60 to 90 minutes. The total dose of alteplase usually ranges from 90 to 100 mg. Allergic reactions and hypotension are rare, and alteplase is not immunogenic.

Tenecteplase

A genetically engineered variant of t-PA, tenecteplase was designed to have a longer half-life than t-PA and to be resistant to inactivation by PAI-1. To prolong its half-life, a new glycosylation site was added to the first kringle domain (see Fig. 151-11). Because addition of this extra carbohydrate side chain reduced fibrin affinity, the existing glycosylation site on the first kringle domain was removed. To render the molecule resistant to inhibition by PAI-1, a tetraalanine substitution was introduced at residues 296 to 299 in the protease domain, the region responsible for the interaction of t-PA with PAI-1.

Tenecteplase is more fibrin specific than t-PA. Although both agents bind to fibrin with similar affinity, the affinity of tenecteplase for (DD)E is significantly lower than that of t-PA. Consequently (DD)E does not stimulate systemic plasminogen activation by tenecteplase to the same extent as t-PA. As a result, tenecteplase produces less fibrinogenolysis than t-PA.

For coronary fibrinolysis, tenecteplase is given as a single intravenous bolus. In a large phase III trial that enrolled almost 17,000 patients, the 30-day mortality rate with single-bolus tenecteplase was similar to that with accelerated dose t-PA.[28] Although rates of intracranial hemorrhage also were similar with both treatments, patients given tenecteplase had fewer noncerebral bleeds and a reduced need for blood transfusions than those treated with t-PA. The improved safety profile of tenecteplase likely reflects its enhanced fibrin specificity. These properties have prompted its recent compression with alteplase in patients with acute ischemic stroke.[29]

Reteplase

A recombinant t-PA derivative, reteplase is a single-chain variant that lacks the finger, epidermal growth factor, and first kringle domains (see Fig. 151-11). This truncated derivative has a molecular weight of 39,000. Reteplase binds fibrin more weakly than t-PA because it lacks the finger domain. Because it is produced in *Escherichia coli,* reteplase is not glycosylated. This endows it with a plasma half-life longer than that of t-PA. Consequently reteplase is given as two intravenous boluses, which are separated by 30 minutes. Clinical trials have demonstrated that reteplase is at least as effective as streptokinase for treatment of acute myocardial infarction, but the agent is not superior to t-PA.[29]

New Fibrinolytic Agents

Several new drugs are under investigation. These include desmoteplase (see Fig. 151-11), a recombinant form of the full-length plasminogen activator isolated from the saliva of the vampire bat,[30] and plasmin derivatives. Desmoteplase, which is more fibrin specific than t-PA, is being investigated for the treatment of acute ischemic stroke, whereas plasmin is under investigation for catheter-directed therapy (see Chapter 145).

CONCLUSIONS AND FUTURE DIRECTIONS

Arterial and venous thrombosis reflect a complex interplay among the vessel wall, platelets, the coagulation system, and the fibrinolytic pathways. Activation of coagulation also triggers inflammatory pathways that may contribute to thrombogenesis. A better understanding of the biochemistry of blood coagulation and advances in structure-based drug design have identified new targets and resulted in the development of novel antithrombotic drugs. Well-designed clinical trials have provided detailed information on which drugs to use and when to use them. Despite these advances, however, arterial and venous thromboembolic disorders remain a major cause of morbidity and mortality. Therefore the search for better targets and more potent or more convenient antiplatelet, anticoagulant, and fibrinolytic drugs continues.

CHAPTER 152

DISORDERS OF COAGULATION IN THE NEONATE

Christine A. Macartney, Nethnapha Paredes, and Anthony K.C. Chan

The neonatal stage is a period of rapid physiologic changes, some of which affect the hemostatic system. The hemostatic system is a dynamic system that evolves gradually from birth into the mature adult form. Evaluation of disorders of coagulation in the neonate requires an understanding of the evolution of physiologic normal values for age, the congenital disorders that present in early life, and the clinical settings common in neonatology that affect hemostasis and thrombosis risks. The rapid evolution of the blood coagulation system after birth leads to a dynamic group of age-dependent reference ranges for the levels of the various components that should be considered physiologically normal. *Developmental hemostasis* is the term applied to the evolution of the hemostatic and fibrinolytic systems through infancy and childhood.

DEVELOPMENTAL HEMOSTASIS

The coagulation system in children provides innate protection from thrombosis without an increased risk for bleeding. The hemostatic system evolves throughout childhood and most rapidly during the neonatal period. Changes in the plasma concentrations of proteins involved in blood coagulation lead to a dynamic group of reference ranges for preterm and term infants. Although different from adult values, these reference ranges are neither abnormal nor pathologic. The relative rarity of hemorrhagic or thrombotic complications in this population argues that the neonatal coagulation system is physiologically replete.

Laboratory Evaluation

The pioneering work of the late Dr. Maureen Andrew paved the way for research into pediatric hemostasis. The concept of developmental hemostasis is now widely accepted, and her seminal papers describing the reference ranges for healthy premature and full-term neonates are still widely quoted.[1,2] Laboratory evaluation of thrombosis or bleeding in neonates must take into account the age-related reference ranges for healthy newborns, which differ significantly from adult levels. Thus prior publications of defined reference ranges for neonates may not be relevant because coagulation assay results vary depending on the type of analyzer and reagents used.[3] Each laboratory that performs coagulation tests on neonatal samples must therefore develop their own age-related reference ranges specific to their analyzer and reagent combination in order to effectively diagnose and manage neonates with suspected hemostatic abnormalities. Neonatal samples should be drawn by experienced staff. Samples are processed in 1-mL tubes containing 0.1 mL of 3.2% buffered sodium citrate, aiming for a final ratio of one part citrate to nine parts blood.

Functional assays are predominantly used in pediatric studies. Although the absolute values are reagent- and analyzer-specific, the changes in functional protein levels lead to corresponding changes in global tests of coagulation. The prothrombin time (PT), expressed in seconds, in full-term neonates is similar to that in adults, despite the fact that neonates have relative deficiencies of the vitamin K–dependent coagulation factors. However, samples from premature infants and cord blood exhibit a prolonged PT compared with adults.[1] The activated partial thromboplastin time (aPTT) is prolonged in newborns, which is attributed to relative deficiencies in the contact factors. Other tests, such as the thrombin time (TT) and thromboelastography, are less sensitive to age-related changes. The TT in neonates is similar to that in adults when measured in the presence of calcium, which compensates for the unique fetal form of fibrinogen that has increased sialic acid content. Thromboelastography values vary very little with age. The template bleeding time is reported to be normal in neonates, but this is an unreliable test in neonatology and is not recommended for bleeding evaluations. Investigations into neonatal hemostatic pathology are limited by the lack of normal reference values for the neonatal population and the difficulties associated with obtaining clean blood samples for testing.

Blood Coagulation Proteins

The synthesis of fetal and neonatal coagulation proteins begins at approximately 10 weeks of gestation, and plasma concentrations of these proteins increase with gestational age. Maternal coagulation proteins cannot cross the placenta. However, maternal drug intake can affect the synthesis of fetal vitamin K–dependent coagulation proteins, with warfarin, phenytoin, barbiturates, and antibiotics serving as examples.

In the healthy newborn, plasma levels of procoagulant factors such as thrombin, factor (F)VII, FIX, FX, and prothrombin (the vitamin K–dependent coagulation factors) and FXI, FXII, prekallikrein, and high-molecular-weight kininogen (the contact factors) are about 50% lower than adult values (Table 152-1).[1,2] The levels rise as the infant ages, and they reach about 80% of normal adult values by 6 months of age but remain decreased throughout childhood.[4] The levels of fibrinogen, FV, FVIII, and FXIII in neonates are similar to those in adults and remain so throughout childhood.[2,4] The levels of von Willebrand factor (vWF) in newborns are about twofold higher than adult values and gradually decrease over the first 6 months of life,[2] whereas the levels of antithrombin (AT) are lower than adult levels in the first 3 months of life and are comparable to the levels seen in patients with heterozygous AT deficiency. The physiologic ranges for coagulation factors in healthy newborns who have received intramuscular vitamin K after delivery are shown in Table 152-2.

Regulation of Thrombin

Despite decreased and delayed thrombin generation, neonates have excellent hemostasis. Thrombin regulation in neonatal plasma is similar to that in plasma from adults who are receiving therapeutic doses of anticoagulants. The concentration of thrombin generated in neonatal plasma is proportional to the available prothrombin concentration, whereas the rate of thrombin generation depends on the level of other procoagulant proteins. Neonatal fibrin clots bind less thrombin than clots formed in adult plasma, in part because of lower levels of thrombin generation. Reduced thrombin generation and less fibrin-bound thrombin may protect neonates from thrombosis.

Table 152-1 Neonatal Versus Adult Hemostasis

Component	Neonatal Versus Adult Level	
Primary hemostasis	↔	Platelet count
	↑	vWF
Coagulation factors	↓	FII, FVII, FIX, FX
	↓	FXI, FXII
	↓ to ↔	FV, FXIII
	↔	Fibrinogen
	↑	FVIII
Anticoagulant factors	↓	TFPI, AT, PC, PS
	↑	α_2M
Fibrinolysis	↓	Plasminogen
	↔ to ↑	PAI

Modified from Guzzetta NA, Miller BE: Principles of hemostasis in children: Models and maturation. *Paediatr Anaesth* 21:3, 2011.
α_2M, α_2-Macroglobulin; *AT,* antithrombin; *F,* factor; *PAI,* plasminogen activator inhibitor; *PC,* protein C; *PS,* protein S; *TFPI,* tissue factor pathway inhibitor; *vWF,* von Willebrand factor.

Thrombin is inhibited by α_2-macroglobulin, AT, and heparin cofactor II. In neonates the α_2-macroglobulin concentration is twofold higher than that in adults. The overall capacity of newborn plasma to inhibit thrombin is similar to that of adult plasma due in part to the increased binding of thrombin by α_2-macroglobulin. Thrombin inhibition by heparin cofactor II is catalyzed by a dermatan sulfate–like proteoglycan, which is produced by the placenta and is found in both the maternal and the fetal plasma.

Regulation of thrombin generation is accomplished by upstream inhibition of the clotting proteins in the prothrombinase and tenase complexes (see Chapters 128 and 129). Plasma concentrations of protein C are low at birth and gradually increase to adult levels by 6 months of age. Although the total concentration of protein S is low at birth, the functional activity of protein S is comparable to that in adults because low levels of C4b-binding protein result in more free protein S. The interaction of protein S with activated protein C in neonatal plasma may be limited by the elevated levels of α_2-macroglobulin. Free tissue factor pathway inhibitor levels are lower than in adults, despite total tissue factor pathway inhibitor levels being similar in neonatal and adult plasma.

The Fibrinolytic System

Although the levels of some of the components of the fibrinolytic system in neonates are different from those in adults, the clinical relevance of this finding is probably minimal. The fibrinolytic system regulates fibrin deposition by generating plasmin, which solubilizes fibrin. At birth the fibrinolytic system has all the key components, but there are important age-related differences in the quantity and quality of the fibrinolytic proteins and enzymes. Plasma concentrations of plasminogen, tissue plasminogen activator (tPA), and α_2-antiplasmin (α_2AP) are decreased, whereas plasma concentrations of plasminogen activator inhibitor 1 (PAI-1) are increased. As well, plasmin generation and overall fibrinolytic activity are decreased.[5] The capacity to generate plasmin in newborn plasma is generally reduced compared with adult plasma, which likely reflects the decreased plasminogen concentration. Despite lower levels of fibrinolytic components, the newborn fibrinolytic system is still effective.

The whole-blood clotting time and euglobulin clot lysis time are global assays of fibrinolytic activity but reflect only part of the physiologic fibrinolytic potential. Maneuvers that induce the release of endogenous fibrinolytic components, such as venous occlusion, desmopressin infusion, or exercise, provide more sensitive measures in vivo fibrinolytic activity.[5]

Plasminogen levels are lower in neonates than in adults, and fetal plasminogen binds to cellular receptors with lower affinity because of its increased sialic acid and mannose content. Whereas healthy neonates have lower plasmin-generating potential than adults, baseline levels of tPA can increase up to eightfold with illness. Neonates with severe plasminogen deficiency have only a minimal increased risk for thrombosis, and most of their clinical findings are the result of impaired extravascular fibrinolysis. The major plasmin inhibitors circulate at near adult levels in the neonate.

Imbalance in the fibrinolytic system, whether hereditary or acquired, can lead to thrombotic or bleeding complications. Hereditary disorders, although rare, include plasminogen deficiency, PAI-1 deficiency, and α_2AP deficiency. The efficacy and safety of fibrinolytic therapy may be influenced by age-dependent differences in the fibrinolytic system. Data are lacking on the optimal doses of fibrinolytic agents for the pediatric population, especially for neonates. The contribution of differences between the neonatal and adult fibrinolytic systems to the protection from thromboembolic complications in childhood remains to be elucidated.

Platelets

The platelet count and mean platelet volume in neonates are similar to those in adults as is platelet ultrastructure. Neonatal platelets exhibit reduced phospholipid metabolism, calcium mobilization, granule secretion, and aggregation in response to agonists compared with adult platelets.[6] Although thrombocytopenia is common in neonates, thrombocytosis is rare and is associated with prematurity.

Platelet function is reduced at birth, which may reflect the platelet activation and degranulation that occurs during labor and delivery. Flow cytometric studies using monoclonal antibodies directed against platelet activation markers indicate that platelets from cord blood or from neonates on the first postnatal day are hyporeactive compared with adult platelets.[6] This hyporesponsiveness is transient, and the platelets regain normal reactivity 10 to 14 days after delivery.

Despite the reduced platelet reactivity at birth, platelet adhesion may be enhanced because of the presence of higher-molecular-weight vWF multimers in the plasma. Consistent with this concept, the bleeding time and the platelet function analyzer (PFA-100) closure time are shorter in neonates than adults.[6] In healthy neonates, enhanced platelet adhesion immediately after delivery may compensate for the reduced platelet activation in response to agonists. Nonetheless, sick neonates may be at an increased risk for bleeding.[6]

If available, the PFA-100 closure time is preferred over the bleeding time as a means of assessing platelet-related hemostasis. Bleeding times are variable in neonates as they are in adults. Consequently the bleeding time is rarely determined. Although the PFA-100 will not detect mild defects in platelet function, such defects rarely cause serious bleeding in neonates.

The Vessel Wall

Studies in vitro and in neonatal animals suggest that the endothelium from neonates has greater antithrombotic potential than endothelium from adult vessels. In both rabbit venous and aortic models, neonatal endothelium expresses more heparan sulfate proteoglycan than adult endothelium, which results in greater AT-mediated anticoagulant activity in rabbit pups compared with adults. Circulating levels of endothelial cell adhesion markers vary with age, implying dynamic expression and/or secretion of these proteins as a function of age.

NEONATAL HEMORRHAGIC DISORDERS

Significant bleeding in neonates should prompt clinical evaluation. In sick infants, acquired factor deficiencies or thrombocytopenia are frequently to blame, but rare congenital factor deficiencies can also manifest with neonatal bleeding. Attention to maternal factors (e.g.,

infection, thrombocytopenia, drugs) is critical when evaluating neonates. Initial empirical therapy consists of platelet and/or factor supplementation, which is often administered while diagnostic studies are under way.

Evaluation of the Bleeding Neonate

Neonatal, peripartum, maternal, and family history are each important in the evaluation of a newborn with hemorrhagic complications. Maternal history of prior pregnancies, medications, and illnesses can provide clues to the hemostatic disorder in the neonate. The family history, such as parental ethnicity and consanguineous marriage, may help to identify congenital bleeding disorders. Maternal infection, drug use, or immune thrombocytopenia can lead to neonatal thrombocytopenia. Maternal deficiency of vitamin K or consumption of drugs that impair vitamin K metabolism can reduce the levels of the vitamin K–dependent coagulation proteins at birth. Vitamin K administration in the delivery room should be confirmed.

On physical examination, the location and characteristics of bleeding (e.g., procedural, mucosal, cutaneous, intraventricular), whether diffuse or localized, and the general appearance of the baby as sick or well will help to identify the underlying etiology of the hemorrhage. In ill-appearing newborns, disseminated intravascular coagulation (DIC) or liver disease may result in acquired factor deficiencies. These disorders tend to present with diffuse bleeding. Well-appearing newborns are more likely to have localized bleeding or ecchymoses because of thrombocytopenia from a transplacental antibody, vitamin K deficiency, or a rare inherited factor deficiency.

Laboratory evaluation of the hemorrhage in newborns should include sepsis evaluation and determination of the platelet count, PT, aPTT, TT, and fibrinogen concentration. If the test results are normal,

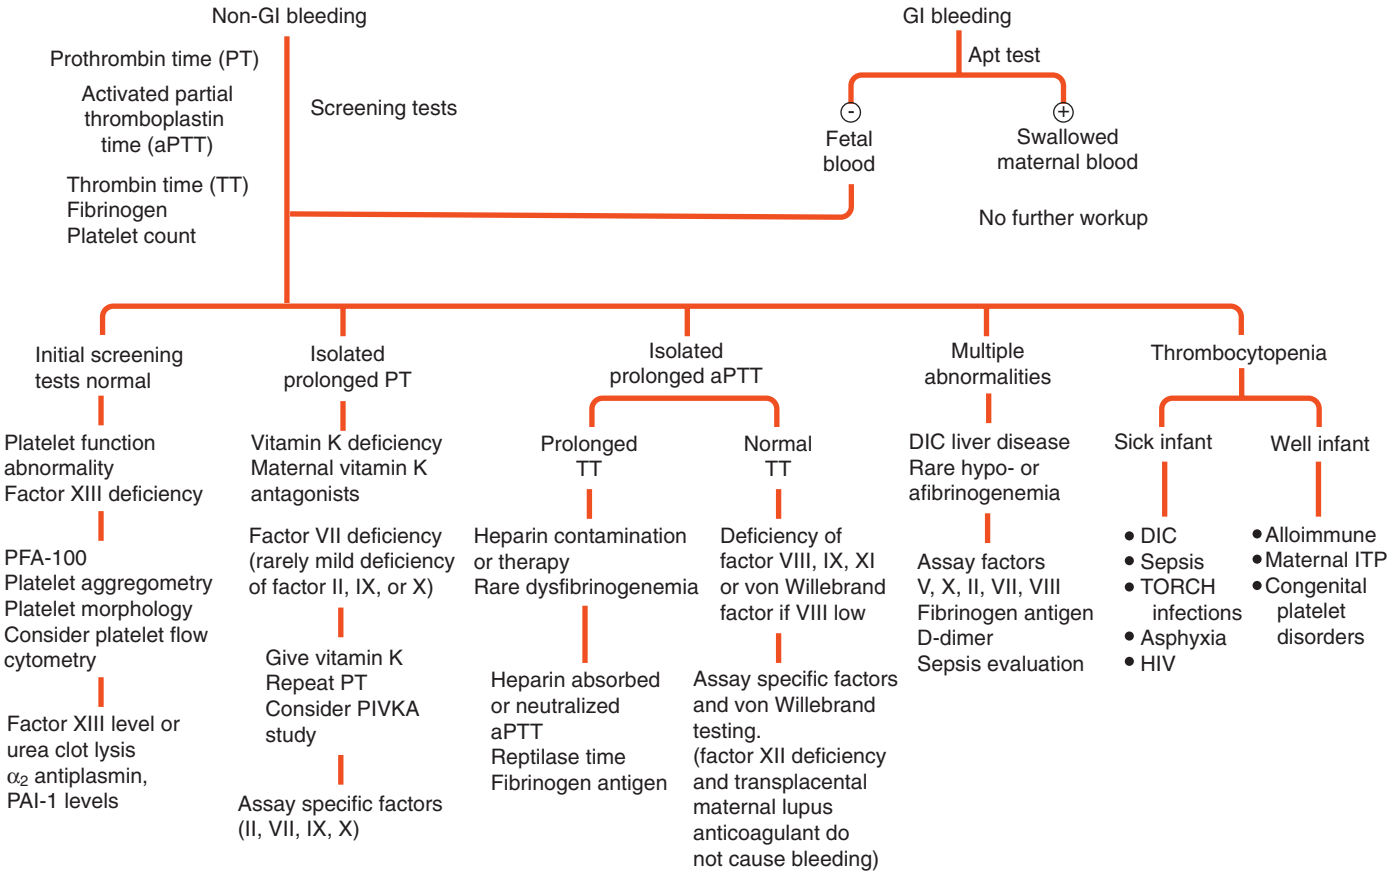

Figure 152-1 DIAGNOSTIC APPROACH TO THE BLEEDING NEONATE. *DIC,* Disseminated intravascular coagulation; *GI,* gastrointestinal; *HIV,* human immunodeficiency virus; *ITP,* immune thrombocytopenia purpura; *PAI-1,* plasminogen activator inhibitor 1; *TORCH,* toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex. *(Modified from Blanchette VS , Rand ML: Platelet disorders in newborn infants: diagnosis and management.* Semin Perinatol *21:53, 1997.)*

bleeding neonates or infants should be assessed for FXIII and α_2AP activity. Deficiencies of FXIII, α_2AP, or PAI-1 are not detected with routine screening, and specific testing is needed if deficiencies are suspected. The approach to laboratory screening is summarized in Fig. 152-1, which has been modified from Blanchette and Rand.[7] Platelet function should be evaluated when primary hemostatic defects are suspected.[8] In male infants with a family history of hemophilia or when hemophilia is suspected, the levels of FVIII and FIX should be determined regardless of the degree of aPTT prolongation.

Neonatal Thrombocytopenia

The following factors are important to consider when evaluating neonates with thrombocytopenia: congenital or acquired, sick or well, maternal antibody or drug, and platelet size. A classification of neonatal thrombocytopenia is provided in Table 152-3. Thrombocytopenia is defined as a platelet count of less than 150×10^9/L.[9] Platelet counts in the range of 100 to 150×10^9/L are common in healthy neonates; these mostly reflect transient thrombocytopenias and require no further investigation unless there is a further decrease in the count. More severe thrombocytopenia (platelet count of $<50 \times 10^9$/L) in neonates rarely manifests with bleeding, particularly in the absence of maternal antiplatelet antibodies. The estimated prevalence of thrombocytopenia is in the range of 1% to 5% of all newborns. The prevalence of thrombocytopenia increases to 22% to 35% in neonates admitted to the neonatal intensive care unit (NICU), with the rates increasing with decreasing gestational age. With severe thrombocytopenia, platelet transfusion may be necessary to treat or decrease the risk for bleeding.

Causes of neonatal thrombocytopenia include decreased platelet production, increased platelet consumption, and/or hypersplenism. Other contributing factors include infection, placental insufficiency, genetic disorders, medications, DIC, or immune deficiency. In well-appearing newborns, thrombocytopenia is usually immune mediated and related to maternal transplacental immunoglobulin G antibodies or drugs (e.g., quinine, hydralazine, thiazides, tolbutamide). In sick newborns, platelet destruction is often related to infection, DIC, extracorporeal membrane oxygenation (ECMO), thrombosis, or mechanical ventilation for hyaline membrane disease. Large vessel thrombosis can also lead to thrombocytopenia, as can specific syndromes, such as renal vein thrombosis (RVT), necrotizing enterocolitis, or vascular anomalies (Kasabach-Merritt syndrome). Platelet production can be impaired with hypoxic-ischemic injury, perhaps because fetal megakaryocytes are particularly sensitive to hypoxia. Newborns from pregnancies complicated by intrauterine growth restriction or pregnancy-induced hypertension frequently exhibit transient mild to moderate thrombocytopenia. Other rare causes of decreased platelet production in neonates include primary congenital platelet or marrow disorders and infiltrative disorders. These are summarized in Table 152-4.

Neonatal Alloimmune Thrombocytopenia

Neonatal alloimmune thrombocytopenia is the platelet equivalent of hemolytic disease of the newborn. The transplacental passage of maternal antibodies directed against fetal platelets that express paternal antigens (HPA) that the mother lacks can result in severe neonatal thrombocytopenia (platelet count $<30 \times 10^9$/L). This may result in major bleeding, particularly intracranial hemorrhage (ICH), which

Table 152-3 Classification of Fetal and Neonatal Thrombocytopenia

	Fetal	Early-Onset Neonatal (<72 hr)	Late-Onset Neonatal (>72 hr)
Conditions	• **Alloimmune** • **Congenital infection** (e.g., CMV, toxoplasma, rubella, HIV) • **Aneuploidy** (e.g., trisomies 18, 13, 21) • Autoimmune (e.g., ITP, SLE) • Severe rhesus hemolytic disease • Inherited (e.g., Wiskott-Aldrich syndrome)	• **Chronic fetal hypoxia** (e.g., PIH, IUGR, diabetes) • **Perinatal asphyxia** • **Perinatal infection** (e.g., *Escherichia coli,* GBS, *Haemophilus influenzae)* • DIC • Alloimmune • Autoimmune (e.g., ITP, SLE) • Congenital infection (e.g., CMV, toxoplasma, rubella, HIV) • Thrombosis (e.g., aortic, renal vein) • Bone marrow replacement (e.g., congenital leukemia) • Kasabach-Merritt syndrome • Metabolic disease (e.g., propionic and methylmalonic acidemia) • Inherited (e.g., TAR, CAMT)	• **Late-onset sepsis** • **NEC** • Congenital infection (e.g., CMV, toxoplasma, rubella, HIV) • Autoimmune • Kasabach-Merritt syndrome • Metabolic disease (e.g., propionic and methylmalonic acidemia) • Inherited (e.g., TAR, CAMT)

Neuroblastoma
Histiocytic lymphohistiocytosis

can occur in 10% to 20% of untreated pregnancies.[9] About half of the cases of neonatal alloimmune thrombocytopenia occur in the first pregnancy. Treatment options include transfusion of antigen-negative platelets if available (HPA-1a ± 5b), administration of high-dose intravenous immunoglobulin and/or a trial of random donor platelets if compatible platelets are unavailable. The recommended dose for intravenous immunoglobulin is a total dose of 1 to 2 g/kg administered as 0.4 g/kg daily for 3 to 5 days or 1 g/kg daily for 1 or 2 days.[10]

Inherited Thrombocytopenia

Most cases of inherited thrombocytopenia are the result of decreased platelet production because of abnormal hematopoietic stem or progenitor cell development. Such disorders are often associated with congenital anomalies, which can direct the course of investigation and aid in the diagnosis.[9] Disorders that present with neonatal thrombocytopenia include Bernard-Soulier syndrome, type 2B von Willebrand disease (vWD), Wiskott-Aldrich syndrome, Fanconi anemia, thrombocytopenia with absent radii syndrome, amegakaryocytic thrombocytopenia with radioulnar synostosis, congenital amegakaryocytic thrombocytopenia, X-linked macrothrombocytopenia due to GATA1 mutation, giant platelet syndromes, Kasabach-Merritt syndrome, thrombotic disorders, and metabolic disorders.

Platelet Abnormalities

Qualitative platelet disorders are rarely associated with overt neonatal bleeding. Patients who present with bleeding and have normal coagulation test results and platelet counts require further investigation. Bleeding may be from mucocutaneous sites, sites of capillary blood sampling, cephalohematoma, umbilical stump, or at sites of procedures. Only the most severe genetic disorders of platelet function present in the neonatal period. These include Glanzmann thrombasthenia and Bernard-Soulier syndrome (see Chapters 127 and 132). Maternal medications may affect platelet function, most notably aspirin, although low-dose aspirin does not appear to alter neonatal platelet function. Neonatal medications may also affect platelet function. Common offenders include nitric oxide, prostaglandin E_2, indomethacin, and aspirin.

Suspected platelet function disorders should be evaluated by platelet morphology and platelet aggregation studies after initial screening by PFA-100. Although PFA-100 testing is a sensitive test for detecting hemostatic disorders in the pediatric population, it is relatively nonspecific. Flow cytometry to evaluate specific surface glycoproteins or electron microscopy studies for granule morphology may be

necessary. Platelet transfusions are often given if bleeding is present. The potential risk for allosensitization from normal platelets in congenital deficiencies of platelet surface antigens must be weighed against the severity of bleeding when functional defects are suspected. Recombinant activated factor VIIa (rFVIIa) has been used to avoid allosensitization.

Vitamin K Deficiency Bleeding

Vitamin K is a necessary cofactor for γ-glutamyl carboxylase, the enzyme required for posttranslational carboxylation of prothrombin, FVII, FIX, and FX, and proteins C, S, and Z. Many newborns are deficient in vitamin K, whether measured in cord blood or indirectly by measuring the levels of vitamin K–dependent coagulation proteins. Vitamin K deficiency bleeding can be acquired or congenital. Risk factors for bleeding include maternal malabsorption, maternal intake of drugs that impair vitamin K metabolism, exclusive breastfeeding, and neonatal malabsorption. Classification is based on the time of presentation. Bleeding in the first 24 to 48 hours of life is usually associated with maternal intake of drugs (e.g., phenytoin, barbiturates, antibiotics), which cross the placenta and impair vitamin K synthesis. Typically bleeding from vitamin K deficiency manifests from days 2 to 7 of life. Gastrointestinal bleeding is the most common presentation, but procedural bleeding, bruising, or ICH can occur. Late-onset vitamin K–related bleeding can occur at up to 12 weeks of age, usually in association with exclusive breastfeeding or with neonatal fat malabsorption, and often manifests as catastrophic bleeding, including ICH. Congenital vitamin K deficiency is an autosomal recessive disorder that occurs because of mutations in the genes encoding γ-glutamyl carboxylase or vitamin K2,3–epoxide reductase complex. Neonates with this disorder often have severe bleeding, including ICH. Genotype analysis is necessary to confirm the defect.[11]

The diagnostic criteria for vitamin K deficiency bleeding include an elevated international normalized ratio (INR) and normal levels of fibrinogen and a normal platelet count. The diagnosis is confirmed if the INR normalizes after administration of vitamin K and the bleeding is stopped. The aPTT is prolonged in severe vitamin K deficiency. Prophylaxis with a single dose of vitamin K (0.5 to 1 mg) in the delivery room prevents early- and classic-onset bleeding. Although oral dosing may be effective because of the potential for impaired absorption, regurgitation, or noncompliance, parenteral administration by the intramuscular, subcutaneous, or intravenous route is preferred. Additional doses of oral vitamin K should be given at days 7 and 28 in breastfed infants.

Vitamin K–induced coagulopathy should be treated with vitamin K, which can be given by intravenous infusion (to minimize anaphylactoid reactions) or by subcutaneous injection. Intramuscular injection should be avoided with severe deficiency because of the potential for hematoma formation. If there is bleeding, fresh frozen plasma (FFP) at a dose of 10 to 15 mL/kg body weight can be given. Because of the potential for thrombotic complications, prothrombin complex concentrates (PCCs) should be reserved for life-threatening bleeding or situations where FFP may produce volume overload. PCC has the added benefit of decreased volumetric load. In the absence of published guidelines, extrapolation from adult data suggests that a PCC dose of 50 units/kg is sufficient. The overall prognosis of vitamin K deficiency bleeding is good.

Inherited Coagulation Disorders

Prolonged aPTT

In neonates the aPTT is physiologically prolonged compared with adult values. Hemophilia is the most common inherited coagulation disorder, as discussed in detail in Chapter 137. Evaluation for FVIII, FIX, and FXI deficiencies should be undertaken immediately in any neonate bleeding with an isolated prolongation of the aPTT or a positive family history. Cord blood samples can be used in those with a family history, thereby avoiding the need for peripheral venipuncture, but careful sampling is important to avoid maternal contamination of the sample. In term and preterm infants, FVIII levels are within the normal adult range despite physiologic differences in the hemostatic system. Thus confirmation of hemophilia A is possible in the neonatal period regardless of gestational age of the child or severity of the condition. However, because the levels of the vitamin K–dependent clotting factors, including FIX, are reduced at birth (and even lower in preterm infants), diagnosis of hemophilia B, particularly mild hemophilia B, is difficult in the neonatal period.

Male newborns with a family history of hemophilia should be evaluated before intramuscular injections, including vitamin K. Typically newborns with hemophilia and bleeding are well appearing. Male infants far outnumber females, given the location of both FVIII and FIX genes on the X chromosome. However, severe FVIII or FIX deficiency can, albeit rarely, present in females, such as in Turner syndrome or extreme lyonization. Approximately one-third of cases of hemophilia are the result of spontaneous mutations; consequently a family history may be lacking. FXI deficiency is an autosomal recessive disorder, so female newborns with bleeding and isolated prolongation of the aPTT should also be tested. Evaluation of hemophilia carrier status in mothers of unknown status (e.g., single prior affected child or positive history in maternal grandmother) can be performed genetically because factor levels in carriers are variable and can overlap with normal levels. Most bleeding episodes in newborn males occur after circumcision or umbilical stump separation, although ICH is reported in approximately 3.5% of hemophiliac newborns,[12] and cephalhematomas are common. Joint bleeding is unusual in the neonatal period. Patients with known or suspected hemophilia and those with severe deficiencies of FVII, FX, or FXIII should be screened for ICH. Although cranial ultrasonography is often used for screening purposes, computed tomography (CT) or magnetic resonance (MR) scanning is more sensitive for detection of small parafalcine bleeds, which can also occur in a small percentage of normal neonates.[8] Neonates with hemophilia A or B are treated with recombinant FVIII or FIX concentrates, respectively. Routine prophylaxis is controversial after uncomplicated term delivery but is recommended for high-risk situations, such as prolonged labor, forceps delivery, or preterm infants.

Isolated Prolonged PT

In term neonates, the PT is normal. Inherited FVII deficiency is a rare, autosomal recessive condition with a strong gene dosage effect. Neonatal bleeding can occur in severe cases (i.e., homozygosity or compound heterozygosity for two mutations in the FVII gene). FVII deficiency can be associated with microcephaly or midline defects because disruption of chromosome 13q can lead to loss of adjacent genes. As a vitamin K–dependent protein, FVII deficiency can occur in association with deficiencies of the other vitamin K–dependent clotting proteins with abnormalities of the vitamin K pathways. Low doses of rFVIIa can be used for treatment of isolated FVII deficiency; FFP and/or vitamin K can be used for management of combined deficiencies.

Prolonged PT and aPTT

The association of bleeding with prolongation of both the PT and aPTT in a healthy newborn may indicate vitamin K deficiency or congenital deficiencies of prothrombin, FV or FX, as well as rare combined deficiencies. Routine prophylactic administration of vitamin K_1 to newborns can complicate the diagnosis of vitamin K deficiency bleeding in neonates.[13] More commonly, combined PT and aPTT prolongation occurs in sick newborns with DIC or severe hepatic decrease. Combined factor deficiencies are rare but must be considered when the laboratory findings or clinical course is confusing. Autosomal recessive mutations in LMAN1 (ERGIC-53) or MCFD2 result in combined FV and FVIII deficiency because of defective intracellular processing of the factors. Mutations in

γ-glutamyl carboxylase are associated with inherited combined deficiencies of all vitamin K–dependent proteins. FVII deficiency has rarely been reported in combination with FV, FVIII, FIX, FX, FXI, and protein C defects, as reviewed by Girolami.[14]

FXIII Deficiency

FXIII is a transpeptidase that cross-links fibrin, thereby rendering it resistant to lysis. FXIII deficiency is inherited in an autosomal recessive fashion, and the prevalence of FXIII deficiency is estimated to be 1 in 3 to 5 million. Homozygotes usually have FXIII levels of less than 1% and have a severe bleeding diathesis. Patients with heterozygous FXIII deficiency are usually asymptomatic but have reduced levels of FXIII.[15] Neonates with FXIII deficiency may present with umbilical bleeding a few days after birth, a frequent finding that occurs in 80% of cases. More severe bleeding, including ICH, occurs in 25% to 30% of patients, a frequency higher than that in patients with hemophilia. ICH is the major cause of death and disability in neonates with FXIII deficiency, and ICH in a child with no other risk factors should prompt a search for FXIII deficiency.

FXIII deficiency is not detected with screening PT, aPTT, or TT assays. Specific assays for FXIII or urea clot solubility testing are used for diagnosis. The clot solubility test is sensitive to very low levels of FXIII (<1%) but is normal if FXIII levels are in the 1% to 3% range. Consequently FXIII immunoassays are perferable.[15]

Treatment of FXIII deficiency includes FFP, cryoprecipitate, or plasma-derived FXIII concentrate. Prognosis is excellent, but affected patients face a lifelong risk for bleeding and those with severe deficiency require prophylaxis.

Other Inherited Deficiencies Associated With Neonatal Bleeding

vWD, which is the most common inherited bleeding diathesis, is in detail in Chapter 140. vWD is rarely associated with neonatal bleeding and may be associated with the most severe subtypes. In a case series that included 55 newborns with vWD, there were no bleeding complications, although cases of scalp hematomas and bleeding after vitamin K injection or umbilical stump detachment were reported. Acquired forms of vWD also are rare but may complicate obstetric management of affected mothers and can affect their newborn babies. A family history of vWD, especially type 2, should prompt vWD evaluation in the neonate before circumcision and possibly before intramuscular injections. There is possible association of vWD with acute idiopathic pulmonary hemorrhage. The diagnosis of vWD may be difficult because vWF concentrations are high at birth and there is a large proportion of high-molecular-weight vWF multimers. Children with a diagnosis of type 3 vWD should be tested for mutations that predispose them to inhibitory alloantibody formation before aggressive replacement with exogenous vWF.[16] Treatment of neonates with vWF involves administration of plasma-derived concentrates that contain vWF (e.g., Humate-P or Alphanate), dosed initially at 40 to 60 ristocetin cofactor units/kg.

Although most of the bleeding problems in neonates are acquired, patients with severe deficiencies of coagulation factors can present in the neonatal period. Autosomal recessive deficiencies, in either homozygous or compound heterozygous state, are grouped as rare coagulation disorders that can manifest as severe bleeding diatheses. In the neonatal period, severe deficiencies of fibrinogen, FVII, FX, and FXIII are the most likely disorders to present with bleeding conditions. One common feature of these disorders is the association with intracranial bleeding.[17] Deficiency of fibrinogen can manifest with bleeding in the soft tissues, after circumcision, or after umbilical stump detachment. The diagnosis can be established with fibrinogen assays, and treatment involves replacement with cryoprecipitate or, if available, fibrinogen concentrate (see box on Recommended Dosing for Transfusion in Neonatal Hemorrhage). Severe FXI deficiency is more prevalent in Ashkenazi Jews and can present with bleeding in newborns after hemostatic challenges, such as circumcision. FV and prothrombin deficiencies are the other rare autosomal recessive homozygous deficiencies that can cause hemorrhagic symptoms.[8]

Not all deficiencies result in a bleeding diathesis. Even complete deficiencies of the contact factors, high-molecular-weight kininogen, prekallikrein, and FXII, are not associated with a bleeding phenotype. Autosomal recessive deficiencies of α_2AP and PAI-1 have been associated with bleeding, but not in the neonatal period.

Liver Disease

Acute liver disease or hepatic failure is uncommon in neonates. Liver disease in neonates may be caused by viral hepatitis, parenteral nutrition, cholestasis, hypoxic injury, or metabolic disease. Rare disorders that cause liver failure in neonates include hereditary tyrosinemia, neonatal hemochromatosis, and hemophagocytic lymphohistiocytosis. Liver dysfunction can affect the hemostatic balance resulting in activation of the coagulation and fibrinolytic systems, reduced synthesis of coagulation factors, poor clearance of activated hemostatic components, thrombocytopenia, platelet dysfunction, loss of coagulation proteins into ascitic fluid, and failure to utilize vitamin K.[18]

Because of reduced synthesis of multiple coagulation proteins, laboratory workup typically reveals a prolonged PT and aPTT. Acute liver disease also results in elevated liver enzyme levels, direct hyperbilirubinemia, and elevated ammonia concentrations. The platelet count may be reduced, especially if hypersplenism is present, and platelet dysfunction is common. Hypofibrinogenemia is a late manifestation of liver disease, and elevated fibrin degradation products and D-dimer occur because of delayed hepatic clearance. Assays of FV, FVII, and FVIII can help distinguish between liver disease, vitamin K deficiency, and consumptive coagulopathy (e.g., DIC). FV and FVIII are not vitamin K dependent. FV is synthesized in the liver, whereas FVIII is synthesized in multiple cell types, and have neonatal concentrations similar to adult levels. Deficiency of all three implies consumption, whereas decreased levels of FV and FVII with a normal FVIII level is consistent with liver disease.

Treatment should include replacement with FFP and/or cryoprecipitate, as well as platelet transfusion. Fibrinogen concentrate has been used as an alternative to cryoprecipitate. Patients with biliary atresia or other cholestatic liver failure syndromes may also benefit from parenteral vitamin K. The outcome is dependent on treatment of the underlying cause of liver disease.

Intraventricular Hemorrhage

Intraventricular hemorrhage (IVH) is associated with significant morbidity and mortality in the newborn period, particularly in premature infants. In the United States, it is estimated that approximately 12,000 premature infants and 20% to 25% of very low-birth-weight infants develop IVH each year. With improvements in neonatal care, the incidence of IVH is decreasing.

The etiology of IVH is multifactorial and includes prematurity of the cerebral vasculature and ischemia-reperfusion injury related to ventilatory support, blood pressure lability, and ECMO. Other risk factors for IVH include vaginal delivery, severe respiratory distress syndrome (RDS), low Apgar scores, pneumothorax, hypoxia, hypercapnia, seizures, patent ductus arteriosus, and infection. Many of these risk factors induce IVH by altering cerebral blood flow. Coagulopathy and thrombocytopenia can contribute to IVH, but their role in the pathogenesis of IVH is uncertain. One study reported hypofibrinogenemia, thrombocytopenia, or prolonged clotting time in 11 of 15 neonates with IVH and in only 5 of 35 unaffected newborns. Hemorrhage complicating cerebral thrombosis may explain some cases of IVH (especially in full-term infants), and heterozygosity for the FV Leiden mutation was reported in 18% of neonates with grade 2 to 4 IVH compared with 3% of controls.

Vitamin K, indomethacin, AT, FFP, FXIII, tranexamic acid, or ethamsylate have all been evaluated for prevention of IVH with

mixed results. Cerebellar hemorrhage should raise suspicion of organic acidemia, such as methylmalonic, propionic, or isovaleric acidemia. rFVIIa may be useful for treatment of IVH, but additional studies are needed to determine its efficacy and safety.

Extracorporeal Membrane Oxygenation

ECMO is occasionally used for treatment of neonates with severe pulmonary hypertension or cardiomyopathy. The ECMO pump, oxygenation membrane, and large-bore catheters can induce thrombosis, which necessitates administration of high-dose systemic anticoagulation, thereby imposing the risk for bleeding. Thrombosis and hemorrhage are common complications in pediatric ECMO patients, particularly if ECMO is initiated after open heart surgery. Approximately 15% of neonates on ECMO sustain an ICH.[19]

With the doses of heparin used during ECMO, the PT and aPTT may not correlate with the activated clotting time (ACT). Furthermore, there is evidence that the heparin dose provides prognostic information in ECMO patients independent of the ACT, suggesting that an ACT of 180 to 220 seconds may not provide adequate anticoagulation. Prolonged ECMO is associated with depletion of clotting factors and high levels of fibrin degradation products. Consequently the aPTT and ACT are prolonged and the levels of D-dimer are increased even when low doses of heparin are administered.

A retrospective study of 29 nonsurvivors of ECMO revealed that most patients have a coagulopathy characterized by a prolonged PT and aPTT, as well as being thrombocytopenic, and most had generally low levels of fibrinogen despite ACT values that were within the acceptable range of 180 to 220 seconds in the final 24 hours of ECMO. Thus routine laboratory testing is inadequate for predicting or preventing thrombotic or hemorrhagic complications in pediatric ECMO patients. Thrombin generation assays, anti-FXa heparin levels, and thromboelastography have been suggested as alternatives to the ACT. Data supporting the use of these tests are lacking.

In neonates with established thrombosis or at risk for thrombosis, daily FFP infusion is sometimes used as a source of plasminogen and anticoagulant proteins. Data supporting this approach are lacking.

Respiratory Distress Syndrome

RDS, also known as hyaline membrane disease, is an acute pulmonary process that is common in premature neonates. The disorder is characterized by hyaline membrane formation and fibrin deposition in diffuse areas of atelectasis. Although increased thrombin generation and decreased levels of AT are found in severe RDS, therapeutic interventions aimed at addressing abnormalities in the coagulation system have yielded inconclusive results. Plasmin or plasminogen may enhance survival; heparin is of uncertain benefit, and AT supplementation may increase mortality. Additional studies are needed to explore the utility of anticoagulant or thrombolytic therapies in RDS. A laboratory profile consistent with mild DIC is common in RDS; fibrinogen levels are decreased, and levels of D-dimer are elevated. An unexpected increase in ventilatory support should raise the suspicion of pulmonary embolism in this population.

NEONATAL THROMBOEMBOLIC DISORDERS

The incidence of thromboembolism in newborns is higher than that in older infants or children. Medical advances have improved neonatal survival at the expense of an increase in the incidence of thrombosis. Venous or arterial access devices are the major acquired risk factor for thromboembolism. The risk is higher in neonates with congenital heart defects or RDS and in those undergoing interventions or ECMO. Dehydration, sepsis, heart failure, congenital nephritic syndrome, necrotizing enterocolitis, and asphyxia are other risk factors for thromboembolism.

Laboratory workup often reveals a hypercoagulable state with a short aPTT; decreased levels of AT, protein C, and protein S; defective fibrinolysis; hyperactive platelets; elevated levels of clotting factors (i.e., fibrinogen, FVII, FVIII); and the presence of antiphospholipid antibodies or thrombophilic defects, such as FV Leiden or the prothrombin gene mutation. A family history of thrombosis or miscarriages may indicate a hereditary thrombophilia.

Consensus guidelines for therapy of neonates with thrombosis have been developed.[20] Heparin, either unfractionated heparin (UFH) or low-molecular-weight heparin (LMWH), remains the mainstay of treatment in newborns. If the thrombus is limb- or life-threatening, thrombolytic therapy may be considered. Because much of the information in this patient population is derived from case reports, case series, registries, and extrapolation from studies in adults, recommendations are mostly of low grade. Large, multicenter, prospective controlled clinical trials are needed to generate evidence-based guidelines; such studies are problematic in neonates.

Incidence

Current estimates of the incidence of neonatal thrombosis are derived from three international registries, each with different inclusion criteria. Based on the data from the German,[21] Dutch,[22] and Canadian[23] registries, it is estimated that clinically relevant neonatal thromboembolism occurs in approximately 24 of 10,000 patients in the NICU and in 0.29 to 0.51 of 10,000 newborn infants. Two-thirds of thromboembolic events are venous, and 80% are either catheter associated or develop after a severe illness.[24] Arterial thromboembolic events in neonates usually present as strokes or emboli to the limbs from catheter-associated thrombi. Neonatal thrombosis is associated with significant mortality and morbidity.

Acquired Thrombophilia

Indwelling Catheters

Central venous and arterial access is essential for the advanced care provided in modern neonatology. The most common acquired thrombotic risk factor in neonates is the presence of an indwelling vascular catheter. The risk for thrombosis depends on catheter location, size, material, duration of placement, and type of fluid delivered. A Canadian registry reported that 80% of episodes of deep venous thrombosis (DVT) in newborns were related to indwelling central venous catheters.[25] Inferior and superior vena cava thrombosis are common complications of central venous catheters, including Broviac and umbilical venous catheters.[23] The incidence of catheter-associated DVT is influenced by the method of detection. When catheters are used for total parenteral nutrition, it is estimated that DVT is diagnosed in 1% on clinical grounds, in 35% by echocardiography, and in 75% by venography. In cases involving central venous catheters, contrast venography is regarded as the reference standard for the diagnosis of thrombosis but ultrasonography is most often used because it is noninvasive, easily performed by the bedside, and there is no ionizing radiation exposure.

DVT often causes pain, swelling, and discoloration of the affected limb. Loss of catheter patency, evidence of collateral circulation, and/or unexplained thrombocytopenia should raise the suspicion of DVT. Prospective imaging studies performed before central access catheter removal demonstrate thrombi in up to 86% of patients.[22] Treatment often begins with removal of the catheter, although consideration of anticoagulation before catheter removal is warranted, especially in infants with right-to-left intracardiac or intrapulmonary shunting. Small catheter-associated thrombi may resolve without specific therapy. Larger thrombi or those in locations associated with greater morbidity (e.g., sinovenous, renal, portal) may warrant short courses of heparin or thrombolytic agents. Platelets should never be administered through arterial catheters because of the potential risk for thromboembolism.

Disseminated Intravascular Coagulation

Neonates are susceptible to DIC because of their immature anticoagulant and fibrinolytic systems. Most cases of neonatal DIC are associated with tissue ischemia and acidosis secondary to sepsis, low-output cardiac failure, perinatal asphyxia, severe RDS, or necrotizing enterocolitis. Other causes of consumptive coagulopathy include large vascular anomalies, severe liver disease, massive hemolysis, or hereditary thrombophilia. DIC may present with hemorrhage and/or thrombosis. Bleeding in a well-appearing neonate is usually the result of an inherited deficiency of a coagulation protein or immune-mediated thrombocytopenia rather than DIC. In contrast, bleeding in a sick preterm neonate is more likely the result of DIC. Patients with DIC often exhibit a prolonged PT, aPTT, and thrombin clotting time, a decreased fibrinogen and FVIII level, thrombocytopenia, and increased levels of D-dimer.

Definitive therapy requires identification and reversal of the trigger for DIC. FFP, platelets (if bleeding is severe), and cryoprecipitate (if the fibrinogen concentration is low) are given to replace the consumed factors. Reasonable treatment targets include maintaining the fibrinogen level over 100 mg/dL, the platelet count over 50×10^9/L, and the PT close to normal. Heparin should be given if there is thrombosis along with AT concentrate if indicated. Successful treatment of DIC depends on reversal of the trigger and provision of aggressive supportive care. Therapy aimed at reversing the coagulopathy has little effect on DIC outcome.

Hereditary Thrombophilia

Spontaneous thrombosis is rare in healthy newborns, and this presentation should prompt evaluation for hereditary thrombophilia. Among the known causes of hereditary thrombophilia, only homozygous or compound heterozygous protein C and/or protein S deficiency is sufficient to induce neonatal thrombosis. Other inherited thrombophilic conditions include FV Leiden, the prothrombin mutation, AT deficiency, elevated lipoprotein(a), maternal anticardiolipin antibodies, and nonspecific inhibitors.

Hereditary thrombophilia should be suspected in patients with spontaneous and extensive thrombosis, ischemic skin lesions, or purpura fulminans. The Subcommittee for Perinatal and Pediatric Thrombosis of the Scientific and Standardization Committee of the International Society on Thrombosis and Haemostasis recommended that pediatric patients with thrombosis be tested for a full panel of genetic and acquired thrombophilic defects.[26] However, because of the difficulty in obtaining a large volume of blood, one can consider performing these tests in stages unless the result of the testing has immediate impact on patient management. On initial presentation of thrombosis, DNA-based assays can be performed. Testing for levels of natural coagulation inhibitors should be delayed until 6 months of age when the levels approach those in adults and until anticoagulant treatment is discontinued.

Specific Neonatal Thrombotic Syndromes

Renal Vein Thrombosis

The renal vein is one of the most common sites of neonatal thrombosis. The incidence of renal vein thrombosis (RVT) is estimated to be 0.5 per 1000 admissions to NICUs and 2.2 per 100,000 live births.[21] RVT is more common in males and in the left renal vein, although 28% to 44% occur bilaterally. In term neonates, RVT usually presents 3 days postnatally; 7% of neonates present with RVT in utero.[27] Clinical manifestations of RVT include hematuria, proteinuria, a palpable abdominal mass, edema, hypertension, renal failure, anuria, adrenal hemorrhage, thrombocytopenia, and anemia. RVT is associated with prematurity, umbilical venous catheters, diabetic mothers, asphyxia, and infections. FV Leiden, prothrombin gene mutation, and elevated lipoprotein(a) have also been found in association with RVT. However, these are common traits, and it would be inaccurate to say they are proven to be causal, despite the associations. Most infants with RVT will experience complete, cortical, or segmental infarction of the affected kidney(s) and/or hypertension.[18]

Diagnosis is reliably confirmed by Doppler ultrasound examination. There are no evidence-based treatment guidelines, and most cases of RVT result in loss of renal tissue regardless of the treatment. Neonates with RVT should be followed for persistent hypertension and progressive renal insufficiency. Unilateral RVT without uremia or clot extension into the inferior vena cava can be managed with heparin or LMWH. Treatment should be given for at least 3 months if there is extension into the inferior vena cava. Bilateral RVT with renal failure should be treated with thrombolytic therapy followed by heparin or LMWH.[20]

Portal Vein Thrombosis

The true incidence of portal vein thrombosis (PVT) is unknown, but it is estimated to range from 1% to 43% of neonates with umbilical venous catheters. The wide variation in incidence reflects differences in imaging protocols. In another study, the incidence of PVT was estimated to be at least 36 cases per 10,000 NICU admissions.[28] When ultrasonography is performed prospectively, 43% of neonates with umbilical venous catheters have asymptomatic PVT.

Major risk factors for PVT include umbilical venous catheters and sepsis/omphalitis. The role of inherited thrombophilia in PVT is controversial. Long-term complications of PVT include lobar atrophy and portal hypertension with associated gastrointestinal bleeding. Complications are more frequent with ectopic umbilical venous catheter placement (below or in the liver) or when thrombi are occlusive. Ultrasonography may reveal evidence of prior PVT with cavernous transformation of the portal vein and subsequent splenomegaly and reversal of portal flow.[29] Spontaneous resolution of PVT is common, but detection of PVT is important, even in asymptomatic patients, because PVT can lead to portal hypertension, which may manifest up to 10 years later.[29] Neonates with umbilical venous catheters should be monitored by ultrasonography, and catheter removal and/or anticoagulation should be considered for PVT.

Purpura Fulminans

Purpura fulminans is characterized by disseminated purpuric lesions, often associated with bullae and necrosis. The histopathology of these lesions reveals diffuse cutaneous microthrombi with surrounding hemorrhage. Diffuse thrombosis, including stroke, retinal infarcts, limb gangrene, and DIC, can occur in purpura fulminans. Causes include severe protein C, protein S, or AT deficiency, either acquired as a complication of sepsis or inherited as homozygous or compound heterozygous conditions. Some infants with severe protein C deficiency do not develop thrombosis until adulthood, suggesting that additional factors influence the neonatal presentation. Treatment with heparin and replacement with protein C concentrate or FFP are indicated. Long-term anticoagulation is often needed.[30]

Arterial Ischemic Stroke

Perinatal arterial ischemic stroke (AIS) is an important cause of cerebral palsy, epilepsy, and cognitive impairment. Perinatal AIS mostly occurs in full-term neonates with a prevalence of 28.6 to 93 cases per 100,000 live births. Presenting features include seizures and lethargy. In the neonatal period, AIS often presents with focal or generalized seizures, although pathologic hand preference before 1 year of age is most common if the stroke was asymptomatic in the newborn period. Ischemic injury is usually detected by MR angiography, and unilateral lesions favor the left hemisphere. Diffusion-weighted MR imaging is superior to cranial ultrasonography or CT scanning.[20]

Risk factors for perinatal AIS are different from thrombosis risk factors in older infants and children because maternal and placental factors play a more important role, and some events even occur in utero.[31] The most common acquired risk factors for perinatal AIS are perinatal asphyxia, fetal distress, chorioamnionitis or other infections, preeclampsia, congenital heart disease, and dehydration. The contribution of congenital thrombophilia to perinatal AIS risk is unclear, although maternal anticardiolipin antibodies may be present for a brief period. In most cases of perinatal AIS, a hypercoagulable state is not detected. One potential mechanism of stroke is embolism of placental thrombi via the umbilical vein and through the patent foramen ovale of the fetus or neonate. Evaluation of placental pathologic conditions is important because demonstration of placental thrombi or abruption may be indicative of maternal prothrombotic state. Furthermore, if placental thrombi are seen histologically, the risk for recurrent events is especially low. Long-term developmental outcomes depend on the extent of the stroke and location of the lesion; strokes involving Broca and Wernicke areas, the internal capsule, or the basal ganglia have a poor outcome.

Treatment depends on whether the stroke is embolic or nonembolic in origin. For nonembolic AIS, current guidelines recommend against anticoagulation or aspirin for neonates with a first AIS, especially if the infarct is large or there is evidence of hemorrhage. Anticoagulant or aspirin therapy is recommended for neonates with recurrent AIS.[20] In a patient with a documented cardioembolic stroke, anticoagulant therapy is suggested.

Sinovenous Thrombosis

Based on data from the Canadian Pediatric Ischemic Stroke Registry, the prevalence of sinovenous thrombosis is 0.67 per 100,000 children, with 43% occurring in the neonatal period.[32] The clinical presentation may be relatively silent, or patients may manifest with diffuse neurologic changes, seizures, and IVH. The most frequently involved vessels are the superior and lateral sinuses, and up to one-third of cases have associated venous infarction and subsequent hemorrhage.[18] Up to 31% of full-term neonates with IVH have associated sinovenous thrombosis, suggesting that the pathophysiology of IVH in full-term neonates is different from that in premature infants.

Risk factors for neonatal sinovenous thrombosis include perinatal asphyxia, diffuse hypoxic injury, dehydration, infection, congenital heart disease, and severe illness, with ECMO now recognized as a specific risk factor. The frequency of hereditary thrombophilias in neonates with sinovenous thrombosis ranges from 20% to 40%, with FV Leiden and MTHFR C677T occurring most often. In contrast to purpura fulminans, no cases of congenital deficiencies of protein C, protein S, or AT have been reported in association with sinovenous thrombosis. Multiple risk factors (maternal, neonatal, perinatal, or prothrombotic) are found in over half of neonates with sinovenous thrombosis.[20] Although the diagnosis of sinovenous thrombosis in neonates is often made by transcranial ultrasonography, MR venography is the most sensitive diagnostic test. Based on data from the Canadian Pediatric Ischemic Stroke Registry, neonatal sinovenous thrombosis is associated with cerebral parenchymal infarcts in 42% of cases, and 83% of these are hemorrhagic infarcts.[32]

Aside from treatment of the underlying conditions, when relevant, there are no standard treatment guidelines. Nonetheless, good results have been obtained with anticoagulant therapy, and UFH or LMWH is given provided that there is no significant ICH. Extended treatment with LMWH or a vitamin K antagonist is recommended for a minimum of 6 weeks and no longer than 3 months.[20] For those with significant hemorrhage, radiologic monitoring at 5 to 7 days is recommended, and anticoagulation should be initiated if there is evidence of thrombus propagation.[20] Anticoagulation is associated with a high rate of hemorrhage, so treatment plans should be individualized. In older patients, punctate hemorrhage behind a cerebral venous infarct is not an absolute contraindication to anticoagulation, but studies in neonates are lacking. Nevertheless, in the Canadian registry, 36% of neonates were treated with UFH or LMWH, mostly for 3 months, and no cases of death or neurologic compromise from hemorrhage were reported.[32] Overall, neurologic impairment was reported in up to two-thirds of cases, and approximately 2% died.

Principles of Therapy

Supportive Therapy

As with other age-groups, therapeutic modalities available to neonates include supportive care, anticoagulation, thrombolytic agents, and surgical thrombectomy. The British Haemostasis and Thrombosis Task Force and the American College of Chest Physicians have proposed guidelines for the management of neonatal thrombosis.[33] Supportive therapy is recommended for clinically silent thrombi, including catheter-associated events. As soon as practical, clotted catheters should be removed, and all documented thrombi should be followed by serial imaging. If venous access is required, one can either monitor the clot closely or provide anticoagulation therapy.

Vitamin K Antagonist Therapy

Vitamin K antagonists, such as warfarin, are not recommended for neonates because liquid preparations are not available, monitoring is complicated, and doses are variable because of alterations in the dietary intake of vitamin K.

Heparin (UFH or LMWH)

UFH or LMWH is the mainstay of anticoagulant therapy in neonates. UFH can be used for the initial treatment of DVT. The rate of heparin clearance is different in newborns compared with adults or older children. Newborns generally have lower levels of AT, which renders them relatively resistant to the anticoagulant effects of heparin. Consequently supplementation with AT concentrate or FFP may be necessary, particularly if there is evidence of heparin resistance. The UFH and LMWH dosing regimens are outlined in the box on Treatment of Neonatal Thrombosis. Anticoagulation is monitored using anti-FXa assays with added AT to compensate for the low levels of AT in neonatal plasma. Therapeutic anti-FXa levels are 0.3 to 0.7 units/mL for UFH and 0.5 to 1 unit/mL for LMWH. The aPTT can also be used to monitor UFH; aPTT values that correlate with anti-FXa levels of 0.3 to 0.7 units/mL are considered therapeutic.

LMWH has emerged as the anticoagulant of choice in the pediatric setting both for prophylaxis and for treatment. The advantages of LMWH include subcutaneous delivery, minimal monitoring, and a lower risk for heparin-induced thrombocytopenia (HIT) and osteoporosis compared with UFH. In the pediatric population, the anticoagulant response to weight-adjusted doses of LMWH appears to be less predictable than that in adults. Prophylactic UFH is recommended to maintain patency of umbilical arterial lines (0.25-1 unit/mL, 25-200 units/kg/day, use lowest dose possible) and for cardiac catheterization (bolus 100 to 150 units/kg with catheter insertion, repeat for prolonged procedures). More studies are needed to define the optimal doses of LMWH. Based on a review of data from 240 neonates treated with enoxaparin, starting doses of 1.75 mg/kg twice daily are recommended for term neonates and 2.0 mg/kg twice daily for preterm neonates, provided that the bleeding risk is low.[34]

HIT antibodies are found in up to 1.5% of neonates, particularly in those who have undergone cardiac surgery. Overt HIT with thrombosis, however, is rare, but it can occur. Mothers with HIT can passively immunize their fetuses. Diagnostic criteria for HIT are described in detail in Chapter 135. Treatment includes cessation of heparin and anticoagulation with argatroban, danaparoid, or lepirudin.[35] Fondaparinux may be a reasonable option in selected cases, but experience in neonates is limited.

Treatment of Neonatal Thrombosis

Unfractionated Heparin
Bolus: 75 units/kg over 10 minutes
Maintenance: 28 units/kg/hr; therapeutic goal, anti-FXa of 0.3 to 0.7 units/mL
Prophylaxis: 10 units/kg/hr
Follow platelet count to detect possible HIT (risk is low)

Enoxaparin
1.5 mg/kg subcutaneously every 12 hours (with normal renal function; round dose to nearest milligram; consider higher dose [see text][34])
Check anti-FXa level by peripheral venipuncture 4 to 6 hours after second or third dose; therapeutic goal, anti-FXa of 0.5 to 1 unit/mL (0.4 to 0.6 unit/mL if concurrent thrombocytopenia or other bleeding risk factor)
Follow platelet count to detect possible HIT (risk is low)
Hold for 24 hours before procedures

Prophylaxis With Enoxaparin
0.75 mg/kg subcutaneously every 12 hours
If checked, anti-FXa level 4 to 6 hours after second or third dose should be less than 0.4 units/mL
Hold for 12 hours before procedures

Purpura Fulminans
Concurrent heparin: UFH dose of 28 units/kg/hr with target anti-FXa of 0.3 to 0.7 units/mL; LMWH dose of 1.0 to 1.5 mg/kg every 12 hours with therapeutic target anti-FXa range of 0.5 to 1 units/mL and replacement with FFP or protein C concentrate
FFP: 10 to 20 mL/kg every 6 to 12 hours for purpura fulminans
Protein C concentrate for severe protein C deficiency: load with 100 to 120 units/kg, then 60 to 80 units/kg every 6 hours × three doses (goal protein C activity 100%). Once therapeutic anticoagulation is achieved, maintenance therapy with 45 to 60 units/kg every 6 to 12 hours (goal protein C activity >25%)

Antithrombin Repletion
Antithrombin (functional) should be maintained at greater than 50% of normal levels for effective heparin-based anticoagulation
Dose in international units = (desired – current AT*) × weight (kg)

AT, Antithrombin; *FFP,* fresh frozen plasma; *HIT,* heparin-induced thrombocytopenia; *LMWH,* low-molecular-weight heparin; *UFH,* unfractionated heparin.
*Expressed as percentage of normal level based on functional ATIII level.

Tissue Plasminogen Activator Thrombolysis for Neonatal Thrombosis

Concurrent Heparin (UFH or Enoxaparin) Should Be Considered at Prophylactic Dosing; UFH Preferred
Life- or limb-threatening thrombi: starting dose of 0.1 to 0.5 mg/kg/hr for up to 6 hours
If no response, consider increase by 0.1 mg/kg/hr increments to maximum 0.5 mg/kg/hr
Consider using fresh frozen plasma 10 mL/kg before thrombolytic therapy
Maintain fibrinogen greater than 100 mg/dL
Maintain platelet count above 100
Reversal of severe bleeding with aminocaproic acid at 100 mg/kg intravenously every 6 hours

UFH, Unfractionated heparin.

Recommended Dosing for Transfusion in Neonatal Hemorrhage

PRBC: 10 to 15 mL/kg single-donor PRBC infused over 4 hours
Platelets*: 10 mL/kg raises platelet count by 75,000 (goal >50,000 if bleeding, >20,000 if not bleeding)
FFP: 10 to 20 mL/kg every 6 to 12 hours for purpura fulminans
Cryoprecipitate: 0.15 units/kg raises fibrinogen about 100 mg/dL (goal >150 mg/dL if bleeding, >50 mg/dL if not bleeding)
von Willebrand factor: 40 to 60 ristocetin cofactor units/kg of plasma-derived FVIII/vWF preparations
Factor VIII: for hemophilia A—50 units/kg load, then 25 units/kg every 12 hours; recombinant factor preferred (monitor FVIII)
Factor IX: for hemophilia B—80 to 100 units/kg daily; recombinant factor preferred (monitor FIX)
Factor VIIa: for severe factor VII deficiency—20 to 30 mcg/kg every 6 to 12 hours

FFP, Fresh frozen plasma; *PRBC,* packed red blood cells; *vWF,* von Willebrand factor.
*Volume limits transfusion of platelets by the "unit" in small neonates. Practices vary—follow institutional guidelines for volume dosing or volume reduction.

Thrombolytic Therapy

Guidelines for thrombolytic management of neonatal thrombosis are provided by the British Haemostasis and Thrombosis Task Force[33] and the Scientific Subcommittee on Perinatal and Pediatric Thrombosis of the International Society of Thrombosis and Haemostasis.[36] Both groups agree that thrombolysis should be considered for extensive thrombosis associated with organ dysfunction or limb-threatening ischemia. Low-dose thrombolysis is recommended to open occluded catheters. tPA is the drug that has been most widely studied in pediatric patients. Transfusion support for hypofibrinogenemia and thrombocytopenia should be provided to minimize the bleeding risk. Contraindications for thrombolytic therapy include active bleeding and major surgery or bleeding within the past 10 days, whereas relative contraindications include severe asphyxia within 7 days, generalized seizures within the last 48 hours, sepsis or prematurity of less than 32 weeks of gestation. If UFH or LMWH is given concomitantly with tPA, it should be administered at prophylactic doses (0.75 mg/kg every 12 hours for LMWH or 10 units/kg/hr for UFH; see box on Tissue Plasminogen Activator Thrombolysis for Neonatal Thrombosis). Surgical thrombectomy is reserved for organ-, limb-, or life-threatening thrombosis when tPA administration is impractical or predicted to be ineffective. Thrombolytic therapy may be of benefit in a select group of pediatric patients with massive pulmonary embolism or extensive DVT.

CHAPTER 153

HEMATOLOGIC CHANGES IN PREGNANCY

Caroline Cromwell

Hematologic conditions are often seen during pregnancy. These range from the simple to the complex. The primary physiological hematologic changes during pregnancy relate to the expansion of plasma volume.[1] In addition to physiologic changes of pregnancy, a prothrombotic state develops as the pregnancy advances that is thought to prepare the mother and fetus for eventual placental separation.[2] All require proper planning, anticipation, and discussion with the treating physicians as well as the patient. The effect of the condition on the pregnancy and conversely the effect of the pregnancy on the condition should be considered. The evolving clinical picture as the pregnancy progresses must also be taken into account. Multidisciplinary planning and communication are essential.

More common hematologic problems and dilemmas in management are discussed in this chapter.

ANEMIA IN PREGNANCY

Anemia in pregnancy is quite common and affects approximately half of all pregnancies worldwide. It is more prevalent in underdeveloped countries.

The World Health Organization classifies anemia in pregnancy as hemoglobin below 11 g/dL, although in developing countries, it is clinically defined as hemoglobin below 10 g/dL.[1] Physiologic anemia occurs during pregnancy as blood volume increases a greater proportion than red blood cell (RBC) mass, resulting in a dilutional anemia. Total circulatory volume increases to approximately 50% greater than prepregnancy volume. Plasma volume and RBC mass return to baseline during the first and second postpartum months. Common maternal signs of anemia include pallor, tachypnea, fatigue, and headache. Hemoglobin levels less than 6 g/dL in pregnant women can be associated with significant maternal and fetal complications. At these levels, tissue oxygenation decreases and may lead to a state of high-output congestive heart failure in the mother.[2-4] Multiple studies have shown a correlation between maternal anemia and increased rates of both preterm (<37 weeks' gestation) and low-birth-weight deliveries.[5-13]

There are varied etiologies behind anemia in pregnancy.

Iron-Deficiency Anemia

Iron-deficiency anemia is the most common cause of anemia in pregnancy. It has been identified as a risk factor for preterm delivery and low birth weight. Iron requirements increase during pregnancy because of maternal and fetal erythropoiesis. Generally, hemoglobin levels decrease throughout pregnancy and then may increase in the last month of pregnancy. Ferritin levels also increase in the last month of pregnancy because it is an acute phase reactant. Erythropoietin levels increase throughout pregnancy. The clinical symptoms of iron deficiency are similar to those in nonpregnant patients and include fatigue, pallor, tachycardia, and poor exercise tolerance. The diagnosis and treatment are generally similar to those in nonpregnant patients. Anemia and a low ferritin level are considered diagnostic. Ferritin levels may be increased in the third trimester.

Because the typical diet in the United States provides only 50% of daily iron requirements for pregnant women and because of the relatively high prevalence of iron deficiency among women of childbearing age, routine iron supplementation in pregnancy is recommended.[16] Currently, the Centers for Disease Control and Prevention, American Dietetic Association, and American College of Obstetrics and Gynecology recommend 15 to 30 mg/day of elemental iron to prevent adverse outcomes from iron-deficiency anemia.[15-19] Treatment should be from the beginning of gestation to 3 months postpartum. Based on the results of a study by Casanueva et al,[20] weekly therapy with 120 mg of iron appears to be a safe and effective alternative to daily therapy. The side effects associated with iron therapy—constipation, diarrhea, nausea—are well known.

Intravenous iron is appropriate in certain circumstances; evidence from a recently published randomized trial by Al et al supports the use of intravenous iron therapy to replenish iron stores in appropriately selected patients, including those who have not tolerated a trial of oral iron therapy and those with severe iron deficiency.[21]

Multiple studies have shown that routine iron supplementation in pregnancy decreases the incidence of iron-deficiency anemia. Furthermore, in a recent randomized, double-blind study in which 275 iron-replete pregnant women received either a daily iron supplement or placebo from the time of enrollment (all women were enrolled before week 20) to 28 weeks' gestation, the incidence of both low-birth-weight and preterm low-birth-weight infants was lower among women who received daily iron.[22] Nonetheless, there are limits to the effectiveness of routine iron supplementation. After all, the recommendation by prominent public health organizations for universal iron supplementation has not led to a commensurate decrease in the incidence of iron-deficiency anemia in pregnancy[23,24] or an increase in maternal hemoglobin levels.[25,26] Compliance is an important factor in this discussion. A large, multicenter, randomized, controlled trial on the benefits of iron supplementation during pregnancy in the United States is needed to draw more definitive conclusions.

Other Nutritional Deficiencies

Folate deficiency and vitamin B_{12} deficiency are the next most common causes of anemia in pregnancy. Cobalamin and folate are critical for fetal growth because they are necessary for the production of tetrahydrofolate. Tetrahydrofolate is key in the DNA synthesis pathway.

Folate deficiency accounts for 95% of megaloblastic anemias in pregnancy.[27] Folate deficiency complicates between 1% and 4% of pregnancies in the United States and affects approximately one-third of pregnancies worldwide.[28] Similar to iron-deficiency anemia, the incidence of megaloblastic anemia in pregnancy is increased in adolescents, women of low socioeconomic status, and women with multiple closely-spaced births.[29] The folic acid requirement for nonpregnant women is 50 to 100 µg/day, but this increases to 150 µg during pregnancy as RBC mass in the mother increases and as fetal demands for folate grow with cell proliferation.[30]

Diagnosis of folate deficiency is best based on RBC folate levels. An elevated homocysteine level also helps confirm the diagnosis. Pregnant women should at least receive 400 μg of folic acid a day. Vitamin B_{12} deficiency is much less common during pregnancy. Diagnosis of vitamin B_{12} deficiency can be aided by the assessment of homocysteine and methylmalonic acid. If a woman is found to be deficient in vitamin B_{12} during pregnancy, vitamin B_{12} injections are indicated. These are usually injected weekly for 4 to 8 weeks and then monthly.

HEMOGLOBINOPATHIES AND PREGNANCY

Sickle Cell Disease

Every year more than 300,000 children are born with either sickle cell disease or thalassemia. Prenatal counseling now exists in many countries. In the United States, all newborns are screened for sickle cell disease. Management of pregnant patients with sickle cell disease requires coordination of care between the hematologist and obstetrician. Many women with sickle cell disease experience more frequent vasoocclusive crises and other sickle cell–related complications during pregnancy.[31] The increased frequency of vasoocclusive crises, particularly during the latter half of pregnancy, likely results from heightened metabolic requirements in pregnancy, increased venous stasis, and the physiologic prothrombotic state of pregnancy. In addition, pathophysiologic changes in the renal and immune function of patients with sickle cell disease increase their susceptibility to urinary tract infections and pyelonephritis. In a recently published retrospective cohort study, Thurman and colleagues[32] compared rates of asymptomatic bacteriuria and pyelonephritis among women with sickle cell trait with those among a cohort of pregnant control patients. The implications of such a study are noteworthy because in the general population, bacteriuria in pregnant women is associated with increased morbidity and mortality for both the mother and fetus. The authors found equivalent rates of asymptomatic bacteriuria in the two groups. On the other hand, they detected a higher prevalence of pyelonephritis among the cohort with sickle cell trait.

Other significant complications occur in pregnant women with sickle cell disease as well. For example, the incidences of preeclampsia, thromboembolic events, placental abruption, intrauterine growth retardation, low birth weight, and postpartum infections are higher among women with hemoglobin SS, SC, and Sb-thalassemia compared with women without sickle cell disease. One study noted a higher incidence of stillbirths and perinatal mortality among patients with sickle cell disease,[33] but another study revealed an increased risk of preterm labor and premature rupture of membranes in women with hemoglobin SS disease.[34] By causing tissue hypoxia, sickling of RBCs within the placental vasculature causes deleterious effects on the fetus.[35]

Because of the increased risk for such complications, women with sickle cell disease should receive close medical attention throughout the prenatal period. This includes counseling about intrauterine diagnosis of sickle cell disease when appropriate. Pregnant women can undergo chorionic villi sampling as early as the ninth week of gestation or amniocentesis in the 15th to 16th weeks. A reticulocyte count along with hemoglobin, iron, and folate levels should be obtained to assess for deficiency states and bone marrow suppression. Urinalysis with urine culture is performed as often as every trimester to monitor for asymptomatic bacteriuria. Finally, beginning around 28 weeks' gestation, patients should make weekly clinic visits and begin serial ultrasonography.

Treatment of sickle cell disease during pregnancy warrants careful consideration. With regard to maintenance therapy, hydroxyurea has been used safely throughout pregnancy in patients with sickle cell anemia, although formal studies of its use in this setting have not been performed to date.[36] Generally, the medication is discontinued. Women should receive 5 mg/day of supplemental folic acid. Studies examining the benefit of prophylactic blood transfusions or exchange transfusions have not led to definitive conclusions.[36] Although they may lead to alloimmunization, prophylactic transfusions appear to decrease the incidence of vasoocclusive crises and decrease maternal and fetal morbidity and mortality.[37] A conservative approach reserves transfusions for patients whose hemoglobin levels fall below 6 g/dL, patients who develop progressive complications related to sickle cell disease, and patients with obstetric complications.[38] Following this approach, 60% to 75% of women with sickle cell disease will require transfusion therapy during pregnancy. Patients with sickle cell crisis during pregnancy should receive aggressive analgesic therapy, hydration, and oxygen while undergoing evaluation of infection or other precipitating influence.

At the time of delivery, pregnant women with sickle cell disease are managed in a manner similar to those with high cardiac output anemia. Supplemental oxygen, hydration, and adequate anesthesia should be given to prevent sickling of RBCs and the associated complications. During the postpartum period, hemoglobin levels are followed closely and prophylaxis for venous thromboembolism (VTE) is administered unless contraindications preclude it.

Thalassemias

Pregnant women with an underlying thalassemia typically have β-thalassemia minor or α-thalassemia trait—conditions with a relatively benign clinical phenotype—rather than β-thalassemia major or hemoglobin H disease. Because of delayed pubertal growth or hypogonadism with associated anovulation, women with β-thalassemia major and hemoglobin H disease rarely become pregnant. Case reports indicate that when it does occur, pregnancy in women with hemoglobin H disease can be complicated by severe hemolytic anemia and hepatosplenomegaly. Pregnancy outcomes among women with β-thalassemia intermedia were examined in a recently published study by Nassar et al. After nine pregnancies in five patients with β-thalassemia intermedia, the authors noted a high incidence of intrauterine growth restriction (IUGR) and frequent requirement for RBC transfusion, even among women who had not been transfusion dependent before pregnancy.[39] One pregnancy resulted in intrauterine fetal demise at 36 weeks. These findings are consistent with previous observations made in reference to a population of pregnant women with thalassemia; an earlier review of the literature found that 50% of pregnancies in this patient population were complicated by preterm delivery, third trimester stillbirth, or IUGR.[40]

Pregnancy is a common setting for the diagnosis of β-thalassemia minor or α-thalassemia trait in previously asymptomatic women who are found to be anemic on routine laboratory evaluation during pregnancy. Several studies indicate that the physiologic anemia of pregnancy may be exacerbated in women with thalassemia minor, although findings from at least one study suggest otherwise.[41] β-Thalassemia minor and α-thalassemia traits do not have an adverse effect on fetal development, fetal morbidity and mortality, or maternal morbidity and mortality.[42]

Similar to those with sickle cell disease, women with thalassemia require vigilant follow-up throughout their pregnancies. This includes interval monitoring of maternal vital signs and fetal heart rate, maternal hemoglobin levels, and fetal growth as assessed by ultrasonography beginning around the 24th week of gestation. Patients are screened for folate and iron deficiency. They should also be assessed for iron overload, which can develop in individuals with thalassemia as a result of increased intestinal iron absorption, frequent blood transfusions, and rapid turnover of plasma iron.[43] Prenatal genetic testing can be performed if desired, with results used to counsel parents of the child and guide optimal care of the fetus. In terms of therapy, there are no specific treatment recommendations for women with thalassemia during pregnancy aside from folate supplementation and supportive care. In pregnant women with evidence of iron overload, chelation therapy using deferoxamine has been safely used, although the potential for teratogenicity associated with the agent must be considered in this setting.[44]

OTHER HEMOLYTIC ANEMIAS

Hereditary Spherocytosis

Hereditary spherocytosis is the most common inherited hemolytic anemia among people of northern European descent.[45] Few cases of pregnancy in individuals with hereditary spherocytosis have been reported. Published reports indicate there may be an increased incidence of first trimester fetal loss in patients with hereditary spherocytosis.[46] Because some patients have only low levels of hemolysis under normal conditions, the disease may not become clinically apparent until pregnancy. Pregnant women with hereditary spherocytosis can exhibit a variety of clinical manifestations. These include folate deficiency related to the increased requirements of pregnancy superimposed on chronic hemolysis, hemolytic crisis, and aplastic crisis.[47,48] The results of two small series suggest that pregnancy outcomes for women with hereditary spherocytosis are generally good, with improvements in outcomes for splenectomized patients.[49] Care is primarily supportive.

Glucose 6-Phosphate Dehydrogenase Deficiency

Favorable pregnancy outcomes observed in women with hereditary spherocytosis and pyruvate kinase deficiency stand in contrast to those in women with glucose 6-phosphate dehydrogenase (G6PD) deficiency. The deficiency of G6PD in this disorder leads to hemolytic anemia in the face of oxidative stress. The condition increases the risk of spontaneous abortion, low birth weight, and neonatal jaundice.[50] Women with G6PD deficiency should be instructed to strictly avoid medications with oxidative potential. Complications after the ingestion of oxidative drugs can even occur in a carrier of the G6PD deficiency gene if her male fetus has inherited the disease.[51]

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria (PNH) is a rare clonal disorder caused by somatic mutation in the membrane-anchoring protein *PIGA*. *PIGA* mutation leads, in turn, to deficient function of critical membrane proteins that in wild-type individuals are anchored by the gene product of *PIGA*. Features of the clinical phenotype include hemolysis, thrombosis, and bone marrow failure. Hemolysis results from deficiency in the membrane proteins CD55 and CD59, which renders affected individuals susceptible to complement-mediated intravascular hemolysis.

The clinical manifestations of PNH can have a devastating impact on pregnancy. Reported cases highlight the significant pregnancy-associated morbidity and mortality in women with this condition. Complications include severe anemia, thrombocytopenia, thrombotic events, preterm delivery, low-birth-weight infants, neonatal death, and maternal death.[52,53] A study by Ray and colleagues[53] reviewed pregnancy outcomes in 24 women with PNH and found a 20% maternal mortality rate.

Owing to the high-risk nature of their pregnancies, women with PNH require close medical attention in the antenatal, perinatal, and postnatal periods. Prophylactic anticoagulation is recommended because of the high incidence of thrombotic events during pregnancy. Warfarin is contraindicated because of its teratogenicity. Low-molecular-weight heparin (LMWH) is favored over unfractionated heparin because it less frequently causes heparin-induced thrombocytopenia. Anticoagulation should be interrupted during the perinatal period but, in the absence of contraindications, reinitiated thereafter and continued for 6 weeks postpartum.[54]

Results of a phase III trial by Hillmen and colleagues[55] demonstrated that eculizumab, a humanized monoclonal antibody against the terminal complement protein C5, can reduce levels of hemolysis, stabilize hemoglobin, minimize transfusion requirement, and improve quality of life in patients with PNH. There are case reports describing success in patients chronically receiving eculizamb throughout pregnancy with uncomplicated deliveries. However, a large randomized trial has not been performed. Supportive care is used as needed throughout pregnancy. RBC transfusions are used in the treatment of anemia. In the setting of thrombocytopenia and bleeding, platelet transfusions may also be necessary.

Autoimmune Hemolytic Anemia

Autoimmune hemolytic anemia can occur during pregnancy and lead to anemia. The relatively small size of immunoglobulin G (IgG) immunoglobulin molecules allows them to cross the placenta; thus the IgG subtype of autoimmune hemolytic anemia can adversely affect fetuses. In contrast, the larger IgM antibodies do not cross the placenta. Patients with autoimmune hemolytic anemia are treated with glucocorticoids and, if necessary, intravenous immunoglobulin (IVIG). Supportive transfusions are administered when needed.[56] In rare instances, pregnancy appears to precipitate the development of autoimmune hemolytic anemia in a previously unaffected woman. The etiology of this phenomenon is not known.[57] Women in this circumstance have been treated in the standard fashion with favorable results.

THROMBOCYTOPENIA

Thrombocytopenia during pregnancy is quite common. It occurs in approximately 10% of pregnancies.[58] Although there is not one clear value to define thrombocytopenia in pregnancy, generally a platelet count less than 100,000 is considered cause for concern. There is some physiologic thrombocytopenia that occurs during pregnancy. Gestational thrombocytopenia (GT) is the most common cause of thrombocytopenia in pregnancy followed by preeclampsia and immune thrombocytopenia. Much rarer causes include disseminated intravascular coagulation (DIC), thrombotic thrombocytopenic purpura (TTP) and hemolytic uremic syndrome (HUS), and medication induced.

The evaluation of thrombocytopenia is essential to rule out any systemic disorders that may affect pregnancy management

Gestational Thrombocytopenia

Gestational thrombocytopenia is quite common during pregnancy. The platelet count is generally never lower than 70,000/μL. This occurs mainly in the third trimester. Patients are asymptomatic and have no history of thrombocytopenia. The platelet count normalizes within 3 months of delivery but often normalizes within 1 week. The etiology of GT remains unclear, but it is thought in part to be autoimmune in nature and demonstrates a clear overlap with mild idiopathic thrombocytopenic purpura (ITP).

The management of patients with GT is uncomplicated. Typically, they can receive epidural anesthesia. However, practice varies at each institution in terms of platelet threshold for epidural anesthesia. Platelet counts greater than 100,000/μL are considered safe for epidural anesthesia. There are studies demonstrating safe administration of epidural anesthesia in pregnant patients with platelet counts as low as 70,000/μL.[60]

Immune Thrombocytopenia

Responsible for pregnancy-associated thrombocytopenia in approximately 3% of cases, ITP represents an important diagnostic consideration in this patient population. It is the most common cause of thrombocytopenia during the first two trimesters of pregnancy.[61] ITP can recur in women with previously documented disease or can develop de novo during pregnancy.

Idiopathic thrombocytopenic purpura is usually not diagnosed during pregnancy. Pregnant patients with ITP usually have a

longstanding history of thrombocytopenia. ITP may be difficult to distinguish from GT because patients with these conditions can present with similar clinical and laboratory findings. Elevated levels of platelet-associated IgG and antibody titers can be found in both conditions.[62] Furthermore, assays that detect antibodies against the glycoprotein receptors IIb/IIIa and Ib/IX are not specific for ITP.[63] Whereas thrombocytopenia in the first trimester or early portion of the second trimester should raise suspicion for ITP, thrombocytopenia that develops later in pregnancy should raise suspicion for GT. A preconception platelet count can also be helpful in distinguishing between the two. It is important to attempt to distinguish between ITP and GT because there is a small but significant risk of neonatal thrombocytopenia in the setting of ITP.[64]

In terms of diagnostic evaluation, HIV, hepatitis, and lupus should be tested for if clinically indicated. Platelet antibody testing is not considered helpful. The peripheral smear may demonstrate an increased platelet size but should otherwise be normal. Bone marrow biopsy and aspirate are not indicated unless there are other hematologic abnormalities present.

Treatment options are generally similar to those for nonpregnant ITP patients (Table 153-1). Platelet transfusions are reserved for life-threatening bleeding because the lives of transfused platelets are usually short in ITP. Glucocorticoids are considered first-line treatment; prednisone is usually initiated at 1 mg/kg based on the patient's baseline weight. Side effects of prednisone should be discussed with the patient and include weight gain, bone loss, hypertension, and gestational diabetes. IVIG can also be used. It is a means of rapid increase in platelet count. It is particularly used to help increase platelet counts a few days before delivery.[65] It is usually administered at a dose of 2 g/kg over 2 days. However, the improvement in platelet count is fairly transient. Splenectomy is also an option indicated for refractory thrombocytopenia; it is best performed during the second trimester.

Other agents such as danazol, cyclophosphamide, and vinca alkaloids—although used in the management of ITP in nonpregnant individuals—are teratogenic and should be avoided during pregnancy.[66] Use of cyclophosphamide has been associated with birth defects. Danazol may cause clitoral enlargement and labial fusion in female fetuses when given in the first trimester.[67,68] The use of rituximab has never been systematically studied in this setting and is considered pregnancy class C. Although case reports exist of its use, it is not generally recommended in this case. Animal data indicates thrombopoietin mimetics may cause fetal harm, and little is known about their use in pregnant patients. A registry has been developed for pregnant patients treated with thrombopoietin mimetics.

As discussed previously, maternal antiplatelet IgG can cross the placenta and cause thrombocytopenia in fetuses. Percutaneous umbilical blood sampling is the most accurate means to obtain the fetal platelet count. However, the procedure is associated with a high complication rate and 1% fetal mortality.[69] Intrapartum fetal scalp sampling represents an alternative, but the accuracy of this technique is only 50% to 70%.[70] The maternal platelet count and antiplatelet antibody level do not accurately predict the fetal platelet count.[71] Overall, 10% of babies born to mothers with ITP have a platelet count less than 50,000/μL, but fewer than 5% have a platelet count less than 20,000/μL.[72] Treatment of pregnant women with IVIG or steroids does not appear to affect the platelet count of fetuses.[72,73] Thrombocytopenia places neonates at risk for bleeding events, including intracranial hemorrhage, although this complication is rare.[74]

Table 153-1 Initiation of Treatment in Pregnant Patients With Idiopathic Thrombocytopenic Purpura

Platelet Count	Treatment
<10,000/μL	Platelet transfusion for life-threatening bleeding
10,000-30,000/μL	Consider monitoring in first trimester; treat in second or third trimester
>30,000/μL	Clinically monitor

In terms of delivery, at present, available guidelines on the subject suggest that obstetric factors, rather than hematologic ones, should guide the manner of delivery.[75] After the delivery of a child, cord blood platelet is checked and the newborn platelet count followed because thrombocytopenia most often peaks 4 to 6 days after delivery and resolves as maternal antiplatelet IgG is cleared.

Preeclampsia and HELLP Syndrome

Thrombocytopenia in pregnant woman also occurs in association with preeclampsia and HELLP syndrome (hemolysis, elevated liver enzymes, low platelet count), potentially severe multisystem disorders associated with pregnancy. In previously healthy nulliparous women, the incidence of preeclampsia is between 2% and 7%.[76] Thrombocytopenia is observed in 15% to 50% of patients with this condition.[59,77] Clinical manifestations include a maternal syndrome characterized by hypertension, proteinuria, and systemic abnormalities as well as a fetal syndrome characterized by fetal growth restriction, preterm delivery, and hypoxia-induced neurologic damage.[76,77]

In most instances, preeclampsia occurs during a woman's first pregnancy, but it can recur in a subsequent pregnancy or occur for the first time in a woman with one or more previously unaffected pregnancies. Risk factors for the disorder include, but are not limited to, preeclampsia in a previous pregnancy, a family history of preeclampsia, chronic hypertension, obesity, multifetal gestation, rheumatic disease, and preexisting thrombophilia.[76] With respect to thrombophilia, a case control study by Mello and colleagues[78] suggests that the prevalence of an underlying thrombophilia is significantly higher among women who develop preeclampsia during pregnancy than among those who have uneventful pregnancies.

HELLP syndrome represents a severe variant of preeclampsia. In the majority of cases, patients who develop the syndrome are white and multiparious.[79] The median age of affected patients is 25 years. The time of presentation during pregnancy ranges from the midtrimester (15%) to term (18%). Thirty percent of patients develop HELLP within 2 days after delivery.[80] Patients typically exhibit vague symptoms such as malaise, fatigue, epigastric or right upper quadrant pain, nausea, vomiting, and flulike symptoms. Because of the nonspecific nature of these symptoms, diagnosis is often delayed; one study found an average time to diagnosis of 8 days in women with HELLP syndrome.[81] Clinical findings at the time of diagnosis—weight gain or edema, hypertension, and proteinuria—are similar to those observed in preeclampsia.[80]

Although various criteria have been used in diagnosing HELLP syndrome, they generally share the following features: signs of microangiopathic hemolytic anemia, serum lactate dehydrogenase greater than 600 U/L or serum total bilirubin greater than 1.2 mg/dL, aspartate aminotransferase greater than 70 IU/L, and a platelet count lower than 100,000/μL.[82] Martin and colleagues[80] have further defined HELLP syndrome on the basis of platelet count. According to this classification, patients with class 1 HELLP syndrome have a platelet count lower than 50,000/μL, those with class 2 disease have a platelet count between 50,000 and 100,000/μL, and individuals with class 3 HELLP syndrome have a platelet count higher than 100,000/μL. As might be expected, women with class 1 HELLP syndrome required a recovery period in the aftermath of their illness.

Although the precise mechanism through which preeclampsia develops is uncertain, research in the field continues to advance understanding of the underlying pathophysiology. Endothelial cell dysfunction after placentation appears to play a central role in the pathogenesis of the disease. During development of the placenta, placental trophoblast cells interface with the epithelial layer of the uterus, forming the decidua. Penetration and remodeling of maternal spiral arteries beginning at week 9 during pregnancy increase placental perfusion and improve oxygenation for the developing fetus under normal conditions.[83]

Cellular abnormalities such as those described impair placental implantation and vasculogenesis, leading to fetal hypoxia and the release of vasoactive compounds such as endothelin, nitric oxide, and

prostaglandins. High levels of endothelin, a potent vasoconstrictor, are seen in preeclamptic patients, and injection of endothelin into rabbits produces a syndrome similar to HELLP syndrome.[84,85] The activity of endothelin, nitric oxide, and prostaglandins leads to hypertension and platelet activation. Angiogenic factors such as vascular endothelial growth factor 1 (VEGF 1) are elevated in preeclampsia compared with normal pregnancy. Injury to the vascular endothelium results in fibrin deposition, further platelet activation, and the release of additional vasoactive agents such as serotonin and thromboxane A_2. The etiology of thrombocytopenia in preeclampsia is likely related to increased antiplatelet IgG levels[86] or to activation of the coagulation cascade with subsequent consumption of platelets.[87,88]

These events lead to the multisystem dysfunction seen in patients with HELLP syndrome. Fibrin deposition in the hepatic sinusoids causes hepatocellular injury. Patients can develop right upper quadrant pain if intraparenchymal or subcapsular hemorrhage occurs. DIC was observed in 21% of patients with HELLP in one series, and placental abruption was seen in 16% of patients.[89] Other manifestations of HELLP syndrome include acute renal failure, pulmonary edema, shock, cerebrovascular accident (CVA), eclampsia, retinal detachment, diabetes insipidus, and increased incidence of cesarean section.

HELLP syndrome is associated with high maternal and neonatal mortality rates. Maternal mortality rates range from 1.1% to 24.2%.[90] The immediate cause of death is most often rupture of the liver, DIC, acute renal failure, pulmonary edema or acute respiratory distress syndrome (ARDS), shock, or CVA. Perinatal deaths resulting from placental abruption, asphyxia, or extreme prematurity occur in 10% to 15% of patients. After delivery, infants born to women with preeclampsia or HELLP can develop a self-limited neonatal thrombocytopenia. Uncertainty exists as to whether infant thrombocytopenia in these instances results from preeclampsia or HELLP itself or from a related complication such as neonatal sepsis.[91-93] HELLP recurs in subsequent pregnancies of affected women in 3% to 27% of cases. There is also an increased risk of preeclampsia, placental abruption, and preterm delivery in these pregnancies.[94-103]

In caring for a patient with preeclampsia or HELLP syndrome, the clinician's primary concerns are the mother's health and safety. The clinician must also consider the stage of pregnancy at time of diagnosis, the condition of the fetus, and desires of the patient in making management decisions. Definitive treatment for preeclampsia and HELLP involves delivery of the fetus; it is indicated for women who present after 34 weeks' gestation and those with evidence of multisystem dysfunction. However, conservative, supportive care without immediate delivery can be pursued for women who are relatively asymptomatic, hemodynamically stable, less than 32 to 34 weeks' gestation, and without evidence of abnormal coagulation.[103,104] Magnesium sulfate, which reduces cerebral vasoconstriction and ischemia, should be administered for seizure prophylaxis.[105] Parenteral labetalol or hydralazine is given for blood pressure control. Systemic corticosteroids appear to lessen the risk of maternal ARDS and reduce neonatal complications when administered to women who present at less than 34 weeks' gestation.[106] In addition to these measures, volume status is closely monitored to prevent overexpansion of plasma volume and ensure adequate urine output.

Persistent right upper quadrant pain—which may herald a liver hematoma or rupture, hemodynamic instability, coagulation profile abnormalities, or a decline in clinical status—should prompt delivery by cesarean section. As mentioned previously, delivery is also indicated if the fetus is at least 32 to 34 weeks' gestation at the time signs and symptoms of preeclampsia or HELLP develop. In a clinically stable woman, vaginal delivery can be attempted.[107] When cesarean section is required, transfusion of RBCs, platelets, and fresh-frozen plasma (FFP) is performed as necessary before and during surgery. Severe hypofibrinogenemia should be treated with cryoprecipitate.

Patients are monitored closely in the postpartum period. Magnesium should be continued for 12 to 48 hours after delivery and blood pressure controlled appropriately. Although hypertension typically resolves within 6 weeks after delivery, some women require long-term antihypertensive therapy.[105] Coagulation and platelet abnormalities tend to resolve within the 24 to 48 hours after delivery. Some patients, however, experience an ongoing decline in the platelet count and should be followed until counts normalize. Postpartum eclampsia can occur for up to 48 hours after delivery; thus patients and health care providers should remain vigilant in monitoring for suggestive signs and symptoms.[108] Treatment options in the setting of severe postpartum preeclampsia and HELLP include corticosteroids and plasmapheresis.[109,110]

In light of the morbidity and mortality associated with preeclampsia and HELLP, considerable research has focused on prevention of these conditions. The efficacy of various preventive strategies, including magnesium supplementation, low-dose aspirin, zinc supplementation, antihypertensive drugs, and heparin therapy among others, has been the focus of observational studies, systematic reviews, and randomized trials. Initial small studies suggested that low-dose aspirin reduces the risk of preeclampsia, although patients who received aspirin had a higher incidence of placental abruption and bleeding.[111-118] Larger, randomized trials failed to confirm the benefit of low-dose aspirin.[112,113]

Thrombotic Thrombocytopenic Purpura–Hemolytic Uremic Syndrome

Thrombotic thrombocytopenic purpura and HUS are also important considerations in the evaluation of pregnant women with thrombocytopenia. Similar to preeclampsia and HELLP syndrome, they are multisystem disorders associated with high morbidity and mortality rates in the absence of appropriate therapy. Microvascular injury and platelet agglutination with resulting thrombocytopenia and microangiopathic hemolytic anemia are pathologic hallmarks of TTP and HUS (Fig. 153-1). They are rare conditions overall, but the incidence of both increases in pregnancy.[119] In the case of TTP, in fact, estimates suggest that approximately 10% of cases occur in pregnant or postpartum women.[120]

Because they share many common clinical features, TTP and HUS are often categorized as a single entity, TTP-HUS. However, the pathophysiology underlying the two conditions appears to be distinctive. TTP is associated with unusually large multimers of circulating von Willebrand factor (vWF), which foster platelet aggregation and thrombus formation. Under normal circumstances, a vWF-cleaving protease referred to as ADAMTS13 (a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13) cleaves these multimers into smaller multimers of normal size. In TTP, function of the cleaving protease is impaired. ADAMTS13 deficiency characterizes familial TTP. Inhibition of ADAMTS13 protease activity by an autoantibody characterizes the acquired form of TTP. An inhibitory autoantibody can be found in 70% to 85% of patients with TTP.[121] On the other hand, impaired vWF-cleaving protease activity does not appear to play a role in the pathogenesis of HUS.[122]

There can be some similarity found between the features of TTP-HUS and HELLP syndrome. It can be difficult to distinguish TTP and HUS from HELLP syndrome because they both have signs of microangiopathy. TTP tends to occur earlier in pregnancy, with a mean onset at 23.5 weeks, although it can occur at any point from the first trimester through the postpartum period.[123] HUS primarily occurs after delivery; 90% of cases occur in the postpartum period, with a mean onset at 26 days after delivery.[124] TTP and HUS do not cause hypertension or liver necrosis. Furthermore, TTP and HUS frequently persist after delivery, but HELLP syndrome typically resolves in the postpartum period.

Treatment of TTP-HUS involves emergent plasmapheresis within 24 to 48 hours of diagnosis. The response rate among pregnant women treated with plasmapheresis for TTP is approximately 75%. By comparison, the overall response rate in patients with TTP is approximately 80% to 90%.[125–128] Long-term sequelae in surviving patients include chronic renal failure, hypertension, and recurrence of TTP-HUS. TTP-HUS recurs in approximately 50% of subsequent pregnancies.[129] Infusion of FFP represents an alternative to plasmapheresis, although plasmapheresis is the preferred treatment modality.

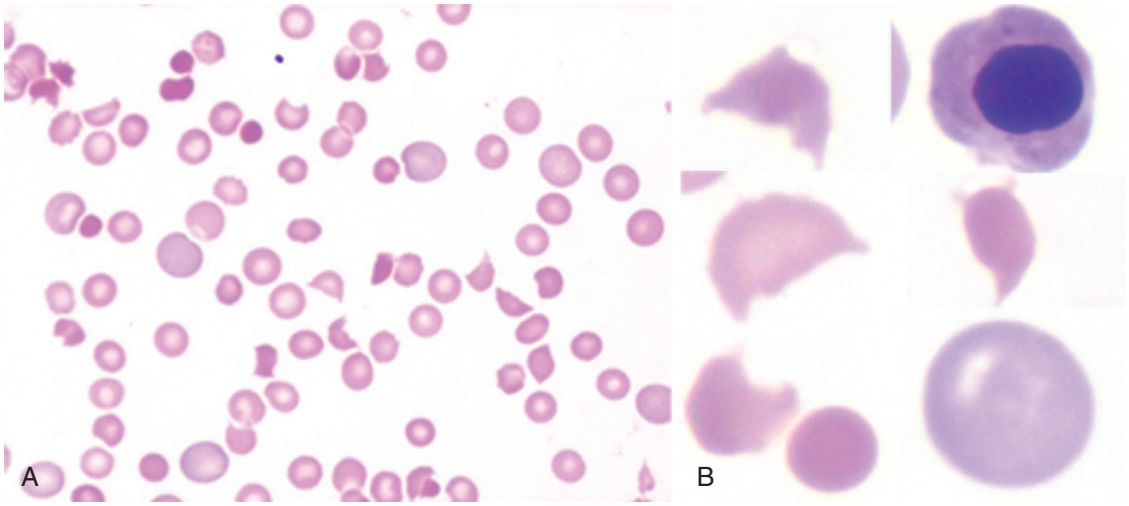

Figure 153-1 MICROANGIOPATHIC HEMOLYTIC ANEMIA. Microangiopathic hemolytic anemia in pregnancy, peripheral blood smear (**A** and **B**). Evidence of microangiopathy with the formation of schistocytes, fragmented forms and spherocytes, associated with polychromasia and nucleated red blood cells (**A** and **B,** detail).

The response rate after FFP infusion is 64%.[130] Corticosteroids (prednisolone 200 mg/day intravenously or prednisone 200 mg/day orally) have also been successfully used in the treatment of pregnancy-associated TTP-HUS, with a response rate of 26%.[128] Conversely, antiplatelet agents such as aspirin do not play a role in the treatment of pregnancy-associated TTP-HUS.[131]

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation in pregnant women can occur in various clinical settings, including HELLP syndrome, TTP-HUS, placental abruption, amniotic fluid embolism, uterine rupture, intrauterine fetal demise, sepsis, elective abortion, and acute fatty liver of pregnancy (AFLP).

Severe placental abruption sufficient to cause fetal death occurs in 0.12% of all pregnancies.[132] This condition leads to a consumptive hypofibrinogenemia, and—when fibrinogen levels fall below 100 to 150 mg/dL—bleeding may ensue. Maintenance of adequate urine output and a hematocrit level greater than 30% are important components of care for women who have had a placental abruption. Either vaginal delivery or cesarean section is appropriate in the context of severe placental abruption. In a woman undergoing cesarean section after abruption, the platelet count should be maintained at 50,000/μL or above through platelet transfusion and fibrinogen replaced with FFP or cryoprecipitate.

Amniotic fluid embolism is a rare but often lethal condition with a mortality rate of approximately 80%.[133] About 10% to 15% of these patients develop a coagulopathy. DIC in this setting most likely follows the release of thromboplastin-rich material into the maternal circulation. DIC seen in association with uterine rupture and intrauterine fetal demise presumably occurs through a similar mechanism.[134] On the contrary, bacterial endotoxin or exotoxin mediates sepsis-associated DIC in pregnant women with pyelonephritis, chorioamnionitis, endometritis, or septic abortion.[135] On rare occasions, elective abortions that use hypertonic solution and those complicated by hemorrhage can be associated with DIC.[136]

Acute fatty liver of pregnancy, or acute yellow atrophy, occurs in one of every 5000 to 10,000 pregnancies, most often in the third trimester of primiparous women.[137] Maternal and fetal mortality are 5% and 15%, respectively. Although the pathogenesis of AFLP is not clear, microvesicular fatty infiltration of the liver's central zone is observed and presumably plays a central role in the development of this disease.[138] In some cases, fatty infiltration can be detected by ultrasonography or computed tomography (CT).[139] Patients present with a variety of symptoms, including malaise, fatigue, right upper quadrant pain, dyspnea, and mental status changes. Laboratory findings include abnormal liver function test results consistent with cholestatic disease, elevated ammonia, low fibrinogen and antithrombin levels, and elevated prothrombin time, with evidence of DIC. Hepatic dysfunction can impair gluconeogenesis. Diabetes insipidus may be present. The clinical course of AFLP resembles those of HELLP syndrome, TTP, and HUS, although the microangiopathy and thrombocytopenia are not as severe.[140] With supportive care, the condition typically resolves within 10 days after delivery.

LEUKEMIA AND LYMPHOMA

The diagnosis of hematologic malignancy during pregnancy can be incredibly traumatic for a pregnant patient and her family, and it is a treatment challenge for the physician. Although great strides have been made in the treatment of this heterogeneous group of diseases, the treatment of pregnant patients is limited because of the lack of research in this area and limited pregnancy safety data. The need to treat the patient and risk to the fetus must both be taken into account. Diagnosis can be difficult because many of the nonspecific signs that accompany these disorders, including fatigue, anemia, loss of appetite, and weight loss, can occur at various times during a normal pregnancy. Diagnostic imaging is mainly limited to ultrasonography and magnetic resonance imaging (MRI). Although the radiation dose from a CT scan is considered low, it is usually avoided. Diagnostic procedures such as bone marrow or lymph node biopsy can usually be safely performed during pregnancy.

In terms of treatment, the risk of teratogenicity from treatment appears highest during fetal organogenesis, which occurs mainly during the first trimester of pregnancy.[141] Ideal dosing is unknown, but dosing is usually based on the woman's prepregnancy weight.

In the largest study of its kind, Aviles and Neri[142] followed 84 children born to mothers with hematologic malignancies, including 29 women with acute leukemia and 38 who received treatment during the first trimester. Assessing growth and development, hematologic parameters, psychological characteristics, and cognitive function over 19 years, the authors found no significant, long-term, deleterious consequences related to treatment. The risk of childhood malignancies was not increased

Hodgkin Lymphoma

That hematologic malignancies are among the most commonly diagnosed cancers during pregnancy reflects to a large extent the relatively

high incidence of Hodgkin lymphoma in women between the ages of 15 and 24 years.[143] Based on the results of several retrospective studies, Hodgkin lymphoma diagnosed during pregnancy appears to have no significant effect on pregnancy outcome.[144] A single-institution experience published by Dilek and colleagues,[145] however, highlights complications that may occur in pregnant women with Hodgkin disease because children born to three of five women with the disease had complications, including death. Remission rates and 20-year overall survival rates among women diagnosed with Hodgkin disease during pregnancy are reportedly similar to those observed in nonpregnant women with the disease.[146,147] In rare instances, Hodgkin lymphoma metastasizes to the placenta, so the placenta and newborn infant should be examined for evidence of malignancy.[148] Staging during pregnancy can be performed with CT, but MRI is preferred to reduce to exposure of the fetus to radiation.

Similar to other malignancies managed during pregnancy, treatment of women with Hodgkin disease is challenging. Generally, chemotherapy at any point in pregnancy increases the risk of an unfavorable outcome.[145] The teratogenic effects of chemotherapy and radiation during pregnancy are a primary concern. However, the standard regimen of Adriamycin, bleomycin, vinblastine, and dacarbazine does not appear to increase teratogenic risk when given in the second or third trimesters.

Non-Hodgkin lymphoma (NHL) rarely occurs during pregnancy. There are case reports and case series of women with NHL who have been successfully treated with chemotherapy during the second and third trimesters of pregnancy.[148] Alkylating agents given in the first trimester can result in fetal malformations or death,[149,150] although there are reports of children who received chemotherapy in the first trimester with no subsequent deficits.[151] Based on the available data, response and recurrence rates among women treated for NHL during pregnancy are similar to those seen in the treatment of pregnant women with Hodgkin disease

Acute and Chronic Leukemias

Treatment of acute myeloid leukemia cannot be delayed. Minimal data are available on the treatment of patients with acute leukemia, but in patients treated with chemotherapy during the first trimester, outcomes were poor. For patients in the first trimester, planned abortion should be discussed, followed by treatment with standard induction chemotherapy.[152]

Patients in the second and third trimesters should be treated immediately. There is an association of preterm delivery, IUGR, and spontaneous abortion with treatment in the second and third trimesters.[153] In terms of treatment options, daunorubicin is preferred because idarubicin has increased placental transfer. Amphotericin B is considered the antifungal of choice in pregnancy because there have been no reports of teratogenicity.[154,155] If treatment is not delayed, pregnant women can have similar outcomes as nonpregnant patients.

Among acute leukemias arising within the myeloid lineage, acute promyelocytic leukemia is unique in terms of clinical features—particularly DIC and associated bleeding complications—and therapy, which involves all-trans retinoic acid (ATRA) in conjunction with traditional chemotherapy. Concern regarding the teratogenic effects of ATRA is warranted. In the 1980s, Lammer and colleagues[156] noted an increased risk of fetal malformation after in utero exposure to the retinoid isotretinoin. And a recent case report by Carradice et al[157] describes a bleeding complication that occurred even after ATRA initiation in a pregnant woman with acute promyelocytic anemia. However, a review of 13 women treated during pregnancy with ATRA for acute promyelocytic anemia found no evidence that the agent leads to fetal malformation when used in the treatment of pregnant women.[158]

Similar concerns regarding toxicity of therapy arise in managing pregnancies conceived before and during treatment of chronic myeloid leukemia (CML). Imatinib, a small molecule inhibitor against the BCR-ABL tyrosine kinase, is the standard of care for treatment of CML. In animal studies, imatinib exhibited teratogenicity in rats and impaired spermatogenesis in dogs, monkeys, and rats.[159]

Imatinib Therapy

A 38-year-old woman with a history of chronic phase CML on imatinib therapy for 5 years becomes pregnant. She has had a complete cytogenetic response. She asks what to do about her imatinib therapy.

Imatinib is teratogenic and should not be used during pregnancy. It has been linked to spontaneous abortions and to fetal malformations including skeletal abnormalities, hydrocephalus, and exopthalmos. While there are case reports documenting fetal exposure at various stages of pregnancy without harm, it is not recommended. Case reports suggest that patients who have achieved maximal response to therapy fare better when their treatment is held for pregnancy, opposed to patients who have not achieved best response.

In a series of 19 pregnancies involving a mother or father undergoing imatinib-based therapy for CML, three pregnancies resulted in a spontaneous abortion, and two others produced children with minor malformations.[160] The remaining 13 pregnancies resulted in the delivery of a healthy child. Among mothers in this study who had previously achieved a complete hematologic remission with imatinib and interrupted therapy during pregnancy, a majority (five of nine) lost the hematologic remission. These findings highlight the important therapy-related implications for mother and fetus, which must be weighed carefully in determining an appropriate course of management (see box on Imatinib Therapy). Currently, it is recommended by specialists in the field that patients undergoing treatment with imatinib for CML use proper contraception.[160]

The Myeloproliferative Neoplasms: Essential Thrombocythemia, Polycythemia Vera, and Myelofibrosis

Essential thrombocythemia (ET) has a bimodal peak of distribution, so it is the most common myeloproliferative neoplasm (MPN) in women of childbearing age. Although evidenced-based guidelines do not exist for the management of pregnancy in this setting, more and more information regarding this topic is being reported.[161] Although some variation is seen in the rates of complications among various studies, overall, all of the studies noted a consistent increase in the rate of complications compared with pregnant women without MPN.[161] Pregnancy alone is a risk factor for thrombosis, and pregnancy confers a sixfold increase in the rate of thrombosis in pregnant patients *without* MPN. Thrombosis is a major source of morbidity and mortality in patients with MPN. It is thought that the prothrombotic state that exists in MPN is behind a majority of the morbidity that can develop during pregnancy. Thrombotic occlusion of placental circulation has been found.

In a study documenting 103 pregnancies occurring in 62 patients with MPN, the rate of live birth was 60%, and the first trimester abortion rate was 32%. Fetal complications occurred in 40% of cases and maternal complications in 9%. The risk of fetal loss for patients with ET was 3.4-fold higher than for those in the aged-matched control population.[162]

A pooled outcome analysis of 461 pregnant patients with ET demonstrated that first trimester loss occurred in 25% to 40% of patients with a live birth rate of 50% to 70%. Late pregnancy loss occurred in 10% of cases.[163] Postpartum thrombotic complications occurred in 5.2% of patients. In a recent analysis of all publications of pregnant patients with ET that had more than 30 patients per study, a mean rate of live birth obtained from the literature was 60.6% (50%-75.4%).[164]

Studies of pregnancy in the setting of polycythemia vera (PV) are much fewer and consist mainly of case reports. One of the largest studies to date consisted of 18 pregnancies. There were 11 live births and seven miscarriages.[165] First trimester loss is the most frequent

complication in patients with PV.[164] Information regarding pregnancy in PMF is even more sparse, with overall fewer than 20 cases reported in the literature. However, based on these, fetal loss is common.[166] In women of childbearing age with an MPN, a discussion when the patient is not pregnant should occur, outlining pregnancy management and risks. Women should be informed if they are taking a drug with teratogenic potential, and the risk of unplanned pregnancy should be recognized.
